Careful physical examination to detect heat, swelling (effusion with or without periarticular fibrosis), and pain with palpation or manipulation is critical for diagnosis of lameness of the metacarpophalangeal joint. However, physical findings may be subtle or seemingly nonexistent, whereas diagnostic analgesia often pinpoints the joint or region as the source of pain. Interpretation of fetlock flexion test results should be made with caution because many horses have false-positive responses to forced flexion of this joint, especially if the toe is used to increase leverage. Pain originating in the limb distal to the fetlock joint often is exacerbated by fetlock or lower limb flexion tests. False-negative responses to fetlock joint flexion also are common, especially in horses with subchondral bone injury and chip fractures. Flexion tests are discussed further in Chapter 8. Increased fluid in the fetlock joint can also be a false localizing sign. The presence of an effusion in the absence of heat and pain may indicate some derangement in synovial function but not necessarily point to the source of a clinically relevant lameness. Lameness characteristically occurs with weight bearing and usually, but not always, is worse with the limb on the inside of a circle. If clinical signs do not adequately localize lameness, perineural or intrasynovial analgesia can specify the region relatively easily. In the absence of localizing clinical signs, the foot and pastern regions should first be eliminated as sources of pain by a midpastern digital nerve block with a dorsal subcutaneous ring. Ideally this is followed by intraarticular analgesia of the metacarpophalangeal joint. If the lameness does not improve within 15 to 20 minutes of intraarticular analgesia, the clinician should perform a low palmar block or palmar and palmar metacarpal nerve blocks. In most horses with intraarticular chip fractures, synovitis, capsulitis, and osteoarthritis (OA), lameness improves after intraarticular analgesia. Horses with major fractures, nonarticular fractures, subchondral bone injuries, and tendon and tendon sheath lesions usually are only markedly improved with perineural analgesia. Perineural techniques are superior to definitively abolish pain associated with the fetlock joint. Pain in horses that do not respond to intraarticular analgesia should not necessarily be presumed to originate elsewhere. False-positive results to intraarticular analgesia can also be obtained; lameness associated with a suspensory branch injury or injury of the proximal aspect of the oblique, cruciate, or straight sesamoidean ligaments may be substantially improved or abolished. Subchondral bone pain will not always, or completely, be eliminated with intraarticular analgesia.

Several techniques are used for intrasynovial analgesia of the fetlock joint. One author (DWR) prefers to inject the local anesthetic solution with the horse's limb on the ground. The dorsal aspect of the fetlock is readily accessible when the horse is bearing weight. As the clinician faces forward and presses the back of his or her arm against the horse's carpus, a 22-gauge, 2.5-cm needle attached to a 75-cm extension set is inserted horizontally into the dorsal aspect of the joint just proximal to the margin of the proximal phalanx and deep to the common digital extensor tendon. One of us (DWR) uses 10 to 15 mL of 2%

mepivacaine, but many practitioners use no more than 6 to 10 mL. One author (SJD) prefers to inject into the palmar pouch through the metacarpomesometacarpal ligament, with the limb flexed, using a 21-gauge, 3.8-cm needle, injecting 6 to 10 mL of 2% mepivacaine depending on the size of the horse. Other techniques are described in Chapter 10.

IMAGING CONSIDERATIONS

The fetlock joint is easy to image accurately because of the size and accessibility. Numerous flexed and oblique radiographic images to specifically silhouette or separate structures help to identify subtle lesions. The same advantages apply to scintigraphic and ultrasonographic imaging. For example, flexed lateral scintigraphic images can help determine whether a lesion in the palmar aspect of the fetlock involves the base of a PSB or the palmar surface of the McIII. A minimum set of radiographs should include dorsopalmar, lateromedial, flexed lateromedial, and both oblique images. The size of the region and absence of overlying soft tissues results in excellently detailed radiographs, even with portable x-ray machines, if suitable screen–film combinations are used or computed or digital radiography is available. A number of specific radiographic images should be obtained if certain lesions are suspected. For example, if a subchondral injury involving the distal palmar aspect of the McIII is suspected, the oblique images should be taken in a more proximal to distal direction than usual. If a lateral condylar fracture is identified, a partially flexed dorsopalmar image should be used to help identify comminution along the distal palmar aspect of the fracture line.^{4,5} Osteochondrosis of the sagittal ridge of the McIII and incomplete sagittal fractures of the proximal phalanx are lesions that can be difficult to identify in overexposed lateromedial images or underexposed dorsopalmar images, but digital radiography has largely eliminated the need to obtain numerous exposures with different techniques. Reference to the location of soft tissue attachments in the fetlock region is necessary for accurate interpretation.⁶

Nuclear scintigraphy has proven to be an exceptionally valuable tool to evaluate the fetlocks of active racehorses because so many injuries involve those joints, especially the distal metacarpal/metatarsal condyles. Flexed lateral images and dorsopalmar/plantarodorsal images allow excellent anatomic discrimination of which specific structures in the fetlock region have increased radiopharmaceutical uptake (IRU).⁷ In particular, flexed lateral and dorsal scintigraphic images can be very helpful to separate palmar metacarpal and PSB uptake. Scintigraphy is also useful for detection of subchondral and trabecular bone injuries in sports horses.^{8,9}

Ultrasonographic evaluation of the fetlock can be valuable for evaluation of tendon and ligament injuries around the fetlock, especially the digital flexor tendons, the palmar annular ligament (see Chapter 74), and the dorsal synovial pad/plica, as well as the bone margins.^{10,11} Ultrasonography (96%) was more accurate than radiology (44%) in predicting the number and location of osseous fragments on the dorsal aspect of the metacarpophalangeal and metatarsophalangeal joints identified using arthroscopy.¹² Three-dimensional imaging modalities such as computed tomography (CT)^{13–15} (see Chapter 20) or

magnetic resonance imaging (MRI) (see Chapter 21) can also be very valuable in the fetlock, especially in areas like the distal palmar McIII condyle, the axial aspect of the PSBs, and the periarticular soft tissues.^{16–19}

TYPES OF FETLOCK JOINT LAMENESS

Most fetlock joint lamenesses can be categorized into one of three types:

1. Acute or repetitive overload injuries without specific fracture or fractures: capsulitis/synovitis, chronic proliferative (villonodular) synovitis, OA, subchondral bone injury without obvious fracture, and sesamoiditis
2. Articular fragments/lesions that can be removed (traumatic and developmental lesions) from the dorsal or palmar aspects of the proximal phalanx; apical, abaxial, and basilar PSB fractures; and fragments from the sagittal ridge of the McIII
3. Major articular fractures (i.e., those that should be repaired), including sagittal and frontal/near frontal (dorsal) plane fractures (mostly seen in the hindlimbs); collateral ligament avulsion injuries (mostly foals and yearlings) of the proximal phalanx; midbody, large abaxial, or basilar fragments of the PSBs; and condylar fractures of the McIII

Conditions specific to the metatarsophalangeal joint and a detailed description of sagittal fractures of the proximal phalanx are discussed elsewhere (see Chapters 35 and 42). Injuries of the digital flexor tendon sheath, superficial and deep digital flexor tendons, the palmar annular ligament, and the proximal digital annular ligament are discussed in Chapter 74. Suspensory ligament (SL) branch injuries are discussed in Chapter 72. Injuries of the distal sesamoidean ligaments are discussed in Chapter 82. Traumatic disruption of the suspensory apparatus is discussed in Chapter 104.

ACUTE OR REPETITIVE OVERLOAD INJURIES

Capsulitis/Synovitis

Clinical Signs

Virtually every young racehorse has one or more episodes of metacarpophalangeal capsulitis or synovitis that is characterized by heat, effusion, and pain with flexion. Overt lameness usually is mild and often not evident after the horse warms up. Signs typically manifest as the horse increases the speed and distance of its exercise regimen. If the typical localizing signs are missed, the major indication may be a decrease in performance. In horses with chronic disease, visible thickening of the periarticular tissues usually is noticeable, with decreased range of motion of the joint. In mature sports horses, capsulitis and/or synovitis is less common as a primary condition but is more likely to be associated with sudden-onset moderate to severe lameness.

Diagnosis

A diagnosis of primary capsulitis or synovitis usually is made by clinical observations and the absence of radiological or scintigraphic bony abnormalities. Synovitis and capsulitis may also accompany other causes of fetlock joint lameness, such as chip fractures. Synovial fluid analysis has not

been particularly useful in diagnosis or prognosis for most fetlock joint injuries except to help identify infection.

Treatment

In most young horses the condition resolves with nonsteroidal antiinflammatory drugs (NSAIDs), adjustments in training, and increased fitness. Intraarticular hyaluronan (20 mg) is helpful in horses with acute, mild to moderate synovitis, but a combination of hyaluronan with a low dose of a corticosteroid (e.g., 3 to 5 mg of triamcinolone acetonide or 20 to 30 mg of methylprednisolone acetate) is more consistently effective in resolving the clinical signs of inflammation. Injection should be followed by a decrease in exercise intensity for at least 1 to 2 weeks. Postexercise icing of the involved fetlock joints can be helpful. Generic OA treatments, including oral glucosamine with or without chondroitin sulfate, intramuscular polysulfated glycosaminoglycans (PSGAGs), and intravenous hyaluronan merit consideration, but they do not usually yield the consistent response seen with intraarticular therapy. Topical application of 1% diclofenac sodium (Surpass, IDEXX Pharmaceuticals, Inc., Greensboro, North Carolina, United States) appears to reduce inflammation.

Chronic Proliferative (Villonodular) Synovitis

Clinical Signs

Chronic capsulitis/synovitis is caused by repetitive injury of the dorsal aspect of the fetlock joint. The lesion is defined by a thickening of the normally dorsally located bilobed synovial pad that hangs down on either side of the sagittal ridge of the McIII. With extreme extension of the fetlock joint, the dorsal rim of the proximal phalanx impinges on the synovial pad, and repetitive trauma results in its inflammation and subsequent fibrosis. The tissue can become so thick that the dorsal profile of the joint is visibly disfigured. The characteristic swelling is asymmetrical on the midproximodorsal aspect of the fetlock (Figure 36-1) rather than simply spherical in outline as in a typical osteoarthritic fetlock joint (this is called an *osselet*). Exercise inflames the tissue further, and clinical signs of lameness or diminished performance can result.

Diagnosis

The diagnosis of proliferative synovitis is based on physical examination, radiography, ultrasonography, or a combination of these modalities. The most common radiological sign of the lesion is a crescent-shaped, radiolucent “cut-out” on the dorsal aspect of the McIII at the level of the joint capsule attachment (Figure 36-2). The proliferative lesion may undergo dystrophic mineralization and be radiologically visible. Radiographic contrast studies can be used, but ultrasonography is simpler and more reliable (Figure 36-3). Normal thickness on ultrasonographic examination has been described as less than 2 mm,^{10,11} but mere identification of a slightly thicker than average structure is certainly not an indication for surgical excision. Many older racehorses have a substantially thicker synovial pad without any associated discomfort. Horses with severe OA have proliferative synovitis in the palmar pouch, and a large concave outline of the distal palmar aspect of the McIII is seen proximal to the PSBs (Figure 36-4 and Figure 34-17), which is associated with a poor prognosis.

Fig. 36-1 • An older Thoroughbred racehorse with chronic proliferative synovitis. The dorsal swellings are firm and localized in the proximodorsal aspect of the joints (arrows).

Fig. 36-2 • Chronic proliferative (villonodular) synovitis of the metacarpophalangeal joint with a typical erosive lesion (arrows) along the proximal dorsal margin of the sagittal ridge of the third metacarpal bone seen in a lateromedial radiographic image. The fibrotic tissue may have small fragments of bone and cartilage or dystrophic mineralization.

Treatment

Treatment for proliferative synovitis usually consists of aggressive intraarticular therapy (e.g., hyaluronan and corticosteroids), rest, and alterations in training. Many horses require frequent medication until the joint becomes stiff enough to prevent dorsal impingement. Horses appear to be able to work through this problem as they develop increasing strength and fitness. If the horse does not

Fig. 36-3 • Transverse (left) and longitudinal (right) ultrasonographic images of the distal dorsal metacarpal region. Ultrasonographic examination can confirm a thickened synovial pad, but the diagnosis usually is made based on physical examination and radiological findings. *McIII*, Third metacarpal bone; *SP*, synovial pad.

Fig. 36-4 • Flexed lateromedial radiographic image of a Thoroughbred racehorse with severe chronic synovitis and osteoarthritis that led to the development of a large erosive lesion of the distal palmar aspect of the third metacarpal (*McIII*) bone. There is a large concave outline of the palmar cortex of the *McIII* just proximal to the proximal sesamoid bones.

respond to medical treatment, surgical excision using an arthroscopic technique is recommended.^{20,21} Surgical debridement must be followed with continued medical treatment and careful attention to the training regimen. It is important to recognize that the thickening of the proximal dorsal synovial pad may be just one part of a chronic, osteoarthritic joint. In such horses, any therapy such as surgery directed solely at this lesion probably will fail.

Osteochondral Fragments in the Synovial Pad

Well-rounded osteochondral fragments in the synovial pad on the dorsoproximal aspect of the fetlock have been described in Warmblood horses in both forelimbs and hindlimbs, either as an incidental finding in presale radiographs obtained at 2 and 3 years of age ($n = 102$) or in association with fetlock joint pain in mature horses ($n = 2$).²² Radiological differentiation between these fragments and

those that are a manifestation of osteochondrosis may not be possible. However, ultrasonographic examination has confirmed their presence within the synovial pad, and this has been verified at arthroscopic examination and by histology. Histological examination revealed that these fragments consistently comprised an osseous center covered with cartilage on one side and surrounded by fibrous tissue. In a study of 127 joints, multivariable analysis of variance showed a significant association between the presence of a fragment more than 10 mm in length and severe synovial proliferation, wear lines on the dorsal aspect of the *McIII*, and cartilage erosions. The long-term clinical significance of such lesions has not been determined. The etiology of these fragments has not been established.

Osteoarthritis

Clinical Signs

OA of the metacarpophalangeal joint is common, especially in racehorses, endurance horses, polo ponies, event horses, and show jumpers. There is usually a progression of disease from medial to lateral, reflecting the biomechanical loading of the joint.²³ The degree of lameness varies from mild to severe depending on the stage of the disease and recent work history. There is often associated synovitis and/or capsulitis, with palpable distention and/or thickening of the joint capsule. However, the absence of joint effusion does not preclude the presence of OA. There is often resentment of passive flexion of the joint and exacerbation of lameness by flexion; however, the absence of these clinical signs also does not preclude the presence of OA. The range of passive joint motion may be reduced because of increased stiffness of the soft tissues on the dorsal aspect of the joint.

Diagnosis

Lameness is usually abolished by perineural analgesia using a “low four-point block,” but the response to intraarticular analgesia is variable, depending on the degree of subchondral bone pain. Increased intraarticular pressure may be a significant contributor to pain and lameness.²⁴ Radiography usually reveals periarticular modeling on the dorso-proximal aspects of the proximal phalanx, medially more than laterally, with or without modeling of the distal dorsal aspects of the *McIII*. There may be thickening of the proximal subchondral bone plate of the proximal phalanx. Subchondral radiolucent areas are rare. With advanced OA there may be supracondylar lysis of the distal palmar aspect of the *McIII* and modeling of the proximal and distal articular margins of the PSBs. In some horses the only radiological change is narrowing of the joint space, reflecting advanced articular cartilage loss and a poor prognosis. It is important not to overlook this and to appreciate its clinical significance.

Treatment

Intraarticular medication with corticosteroids (triamcinolone acetonide) and hyaluronan or PSGAGs is usually effective in early OA, combined with correction of any foot imbalance. Modification of the training program and selection of work surfaces may be important. Local therapy (e.g., whirlpool boots, spa therapy) can be of benefit. The value of oral nutraceuticals is difficult to quantify but may have

a management role. Autologous conditioned serum (interleukin-1 receptor antagonist) is being used with increasing frequency with anecdotally favorable results. If the clinical signs are inconsistent with the radiological abnormalities or there is a poor response to treatment, further investigation by exploratory arthroscopy (in the presence of joint effusion) or MRI (in the absence of joint effusion) may be warranted.

Traumatically Induced Cartilage and/or Subchondral Bone Injury

Trauma to the fetlock, the result of hitting a jump, getting a show jump pole tangled between the forelimbs, falling, or stumbling, may result in sudden onset of lameness associated with effusion of the metacarpophalangeal joint.^{8,25} Lameness is abolished by intraarticular analgesia. At the time of acute onset of lameness there may be no detectable radiological abnormality, and follow-up radiographs may also have no detectable lesion. Although there may be a transient response to intraarticular medication, effusion and lameness usually persist. Exploratory arthroscopy may reveal a focal area of cartilage loss usually on the dorsal distal aspect of the condyle of the McIII, with exposure of subchondral bone, and some softening of the immediately surrounding articular cartilage or peeling off of a large piece of cartilage—a “delamination” injury. Debridement of such lesions invariably results in clinical improvement. If the lesion is located dorsal to the region of maximum weight bearing, the horse may become sound, but lesions on the major weight-bearing aspect result in a guarded prognosis for return to full athletic function.

Alternatively, follow-up radiographs may reveal a radiolucent area in the subchondral bone of the distal aspect of the McIII, seen best in a dorsal 25° proximal-palmarodistal oblique image. Such osseous cystlike lesions are usually associated with an overlying area of full-thickness cartilage loss. Like the cartilage lesions described above, lesions on the weight-bearing part of the McIII usually result in persistent lameness, but some horses have returned to full athletic function following debridement of more dorsally located lesions. However, the presence of extensive wear lines in the articular cartilage reflecting concurrent OA warrants a guarded prognosis. Trauma through an accident while jumping has also resulted in osseous fragmentation of the dorsoproximal medial or lateral aspects of the proximal phalanx. High-detail radiographs may be necessary to differentiate this fragmentation from periarticular osteophyte formation. However, the immediate recognition of such radiological abnormalities soon after an accident is diagnostic of traumatic joint injury rather than OA. Such fragmentation may be associated with a traumatically induced deep groove in the opposing articular cartilage of the distal aspect of the McIII; therefore, although arthroscopic removal of the fragments is likely to result in clinical improvement, long-term repeated intraarticular medication of the joint is likely to be required to maintain soundness. Secondary OA may ensue.

Subchondral Bone Injury

Clinical Signs

Subchondral bone injury is an extremely important cause of lameness involving the metacarpophalangeal joint,

especially in racehorses.^{26,27} Similar lesions are being recognized with increasing frequency in elite endurance horses and also in other sports horses. There are no specific localizing clinical signs in many horses other than variable lameness and an observable diminution in performance. Signs such as heat, swelling, or response to flexion can be absent or extremely subtle, even in horses with overt lameness. Although subchondral bone injury is far more common in racehorses, it appears that single-step overload injuries that focally damage a portion of the McIII or the proximal phalanx can occur in nonracehorses. Such injuries may result in radiologically visible increased radiopacity or radiolucency. The severity of the lameness in such horses can be surprising, and infection may be a differential diagnosis.

Diagnosis

The inconsistent response to local analgesia can make diagnosis difficult unless a reasonably high index of suspicion for these lesions is maintained. Many horses do not achieve soundness with intraarticular analgesia. Horses with full-thickness cartilage injury overlying the subchondral injury may be most likely to experience improvement in lameness because of the access of the local anesthetic agent to the site. Lameness in most horses improves dramatically with low palmar analgesia (four-point block); however, subcarpal analgesia of the palmar metacarpal nerves is sometimes required for complete resolution of lameness.

The two most common locations for subchondral injury of the fetlock in racehorses are the distal palmar aspect of the McIII and the proximal phalanx under the center of the weight-bearing portion of the medial or lateral articular surfaces. The palmar McIII lesion appears to develop as a focal overload injury where the base of the PSB impacts during maximal weight bearing.^{15,16} In this location, linear or crescent-shaped lucencies are the most common indications of a major advanced subchondral bone injury (Figure 36-5). These often can be seen on a lateromedial image, but special radiographic images may improve the likelihood of seeing a lesion. A slightly flexed, horizontal beam dorsopalmar image silhouetting

Fig. 36-5 • Lateromedial radiographic image of a metacarpophalangeal joint. Subchondral crescent-shaped (arrow) and linear radiolucencies in the distal palmar articular surface of the third metacarpal bone are important radiological findings. Most horses with such lesions have clinical signs of fetlock pain, especially with hard training. The cartilage overlying such lesions is damaged and often unstable.

Fig. 36-6 • Slightly flexed dorsopalmar radiographic image of the metacarpophalangeal joint is helpful to define lesions (arrow) of the distal palmar aspect of the third metacarpal bone.

the distal palmar aspect of the McIII can help define an irregular subchondral outline (Figure 36-6).^{4,5} Oblique images obtained in a slightly (25 to 30 degrees) proximal-distal direction also allow a better evaluation of the palmar aspect of the condyle and the identification of radiolucent defects (see Figure 42-1).⁷ With lesions of the proximal phalanx, an increase in subchondral radiopacity may be evident before radiolucent lesions develop, but increased radiopacity in the McIII is much more difficult to recognize, and differentiation between normal adaptive modeling and injury is not easy.

Scintigraphy is the most sensitive routine diagnostic tool and can identify lesions in racehorses well before radiological lesions are evident (Figure 36-7). Scintigraphy can also be useful in sports horses (positive in 12 of 15 horses with subchondral and trabecular bone lesions detected using MRI), but if trabecular sclerosis is the principal lesion, then scintigraphy may be negative.⁸ Even arthroscopic diagnosis can be difficult in the fetlock joint because the anatomical location of these lesions makes evaluation difficult. If the lesions are accessible, the overlying cartilage may be thin or discolored. The amount of cartilage fibrillation or crazing of the joint surface is variable. MRI is expensive but provides more detailed information about the precise location of injury and some information about the type of bone injury, distinguishing early phases of repetitive stress injury (see Figure 107-7).¹⁶⁻¹⁹ MRI may reveal areas of reduced signal intensity in T1- and T2-weighted images consistent with mineralization (so-called sclerosis or densification) of the bone. There may also be areas of high signal intensity on fat-suppressed images and low signal intensity on T1-weighted images that may reflect bone edema, hemorrhage, fibrosis, or necrosis. High-field images may also reveal areas of cartilage pathology.

In 13 sports and pleasure horses, MRI revealed areas of thickening of the subchondral bone plate and altered signal intensity in the trabecular bone, with mild lesions of one of the collateral ligaments in 5.¹⁶ Mediolateral distribution of injuries was similar. Six of 13 horses returned to full function with conservative management.

Fig. 36-7 • Typical scintigraphic appearance of repetitive stress injury to the distal palmar aspect of the third metacarpal bone. The pattern of increased radiopharmaceutical uptake is made more definitive by comparing standing and flexed lateral images.

Treatment

Rest, or at least decreased training intensity, is the most common recommendation for subchondral bone injury in racehorses. It is currently very difficult to define which horses with injury of this location are going to develop more serious problems such as condylar fractures if they continue in hard work. However, in a recent post mortem MRI study of horses ($n = 47$) subjected to euthanasia on a UK racecourse as a result of a lateral condylar fracture, compared with the contralateral limb ($n = 46$) and a limb from control horses subjected to euthanasia for unrelated reasons ($n = 98$), a combined thickness of the subchondral bone and trabecular mineralization of the palmar aspect of the condyle of the McIII of more than 2 cm resulted in an odds ratio for fracture of 4.23 compared with controls.²⁸ Medications such as bisphosphonates (tiludronate), isoxsuprine, and aspirin are frequently recommended; however, there is little information to support their efficacy. Damaged bone can heal if the horse is rested, but the prognosis depends on the amount of structural damage to the overlying cartilage and any loss in the normal architecture of this critical area.

INJURIES TO THE PROXIMAL PHALANX

Osteochondral Fragments: Dorsoproximal Aspect of the Proximal Phalanx

Clinical Signs

The most common chip fracture in Thoroughbred (TB) racehorses involves the proximal dorsal aspect of the proximal phalanx and is an important differential diagnosis in

any young TB with acute swelling or heat in a metacarpophalangeal joint. Affected horses rarely are lame for more than 2 days after a fracture and may never show overt lameness. An observant groom or trainer may notice an effusion with some heat, and forced flexion usually causes a painful response. Common historical findings include diminished performance, refusal to change leads, and bearing in or out, especially in the stretch.

Dorsal chip fractures can also be seen in yearlings and nonracehorses as an incidental finding. Most presumably occur as a traumatic event during early development and simply go unrecognized until presale radiographs are obtained. Juvenile fragments occur equally in the forelimbs and hindlimbs, whereas traumatic injuries in active racehorses and sports horses are more common in the forelimbs.

Diagnosis

Chip fractures of the proximodorsal aspect of the proximal phalanx of any size are not difficult to diagnose if they are displaced, but nondisplaced fragments may require nearly perfect radiographs. Most chips occur on the prominence just medial to the median sagittal groove of the proximal phalanx. The left forelimb is slightly more commonly affected than the right forelimb in North American TBs. Bilateral chips are fairly common, and thus radiographs of both fetlocks should be obtained before surgery is performed. The fragments generally are seen best on a dorsolateral-palmaromedial oblique or lateromedial image, depending on the obliquity of the fracture line and image (Figure 36-8, A and B). Correct radiographic technique is especially important for small chips because overexposure burns out the lesion on a lateromedial image and underexposed oblique images do not have enough penetration. Although most radiologically diagnosed fractures are dorsomedial, it is important to evaluate arthroscopically the entire dorsal rim of the proximal phalanx because small chondral fractures are common. Horses in which a dorsolateral fragment is seen radiologically usually also have a

lesion on the dorsomedial side. Finally, it is fairly common for fractures to be more evident on early radiographs than on follow-up images because they can become crushed into much smaller fragments pushed back down into the original fracture bed following exercise.

Treatment

Treatment for horses with these chip fractures is less controversial since the advent of arthroscopy. The previous morbidity associated with large incisions on the dorsal aspect of the fetlock to remove rather small fragments made surgical treatment much less attractive. With arthroscopic technique, however, the fragments can be easily and atraumatically removed. An excellent prognosis after a short (approximately 4 to 6 weeks) postoperative convalescence can be given if there are no other degenerative changes in the joint.²⁹⁻³¹ In economically unworthy animals, a period of 3 to 4 months' rest, followed by intraarticular medications as needed, also affords a favorable prognosis, especially if the fragment is not markedly displaced. In our opinion, superior conditioning when these horses return to work helps prolong careers. Injecting a horse with a corticosteroid after it develops an acute chip fracture also can achieve a favorable short-term result and is always a consideration if the horse's immediate racing demands will not allow a substantial period of rest. However, training and racing a horse with an unstable chip fracture may lead to more rapid degenerative changes in the fetlock. Such horses often have extensive score lines, thin cartilage, and more advanced osteoarthritic changes if the fragment is removed arthroscopically at a later date.

Short Sesamoidean Avulsions (Osteochondral Fragments) from the Palmar Aspect of the Proximal Phalanx

Clinical Signs

Characterization of osteochondral fragments arising from the proximal palmar aspect of the proximal phalanx is

Fig. 36-8 • Proximal dorsomedial osteochondral fragments of the proximal phalanx are the most common chip fracture in Thoroughbred racehorses and can be seen on lateromedial (A) and dorsolateral-palmaromedial oblique images (B).

Fig. 36-9 • A typical osteochondral fragment avulsed from the proximal palmar/plantar margin of the proximal phalanx. In the dissection, the attachment of the fragment to the base of the sesamoid by the short sesamoidean ligament is evident, as is the smoothly remodeled defect in the rim of the proximal phalanx.

somewhat controversial. Many consider these fragments to be manifestations of osteochondrosis because they are recognized in very young, untrained animals. It seems most probable that the fragments result from avulsion of a portion of the incompletely ossified proximal phalanx followed by development of a traumatic secondary ossification center.^{32,33} The fragments are consistently attached to the short sesamoidean ligament and there is often a small defect in the proximal aspect of the proximal phalanx (Figure 36-9). These fragments are much more common in the hindlimbs (see Chapter 42) and most common in the Standardbred (STB) racehorse. They are also commonly recognized in European Warmbloods. Medial fragments are more common than lateral, but fragments can be numerous and in several limbs. These fragments often are found on presale radiographs, and the relevance to lameness should always be questioned. Many successful athletic horses perform with these lesions. Racehorses in which the fragments affect performance rarely show overt lameness. TBs may be unable to maintain a straight path or fail to change leads properly, and STBs tend to ride a shaft or take a line. Horses in which the lesions cause clinically significant lameness usually have an effusion. Most are not painful to fetlock manipulation. It is possible for fragments in this location to be acute avulsions in older horses, and it is also possible for a fragment that was previously clinically silent to become displaced and painful.

Diagnosis

Oblique radiographic images are best for delineating fragments arising from the palmar proximal aspect of the proximal phalanx. A flexed image helps to further separate the fragment from the base of the PSBs. This separation is useful with proliferative change at the distal dorsal margin of the PSBs or small, basilar sesamoid fractures. Proximal phalangeal fragments usually are well rounded but can also have odd polygonal shapes.

Training a horse after intraarticular analgesia and recognition of improvement in gait should be diagnostic, but the subtle nature of the lameness can make this difficult. Clinical improvement after empirical intraarticular medication also supports the relevance of a radiological

lesion. Scintigraphic localization of a lesion may also help confirm the diagnosis, but IRU may be only mild or increased in other parts of the joint, making diagnosis difficult in many racehorses.

Treatment

Treatment consists of arthroscopic removal of the lesion if the clinician is confident that the fragment or fragments are the source of pain causing lameness or if the horse is going to public sale. The most common situation is that the fragments are identified before a horse enters training and the fragments are removed prophylactically. Arthroscopic removal is much less traumatic than arthrotomy for this type of lesion. The prognosis is excellent if the lameness diagnosis is correct.³⁴ If good arthroscopic technique with minimal soft tissue trauma is used, horses require a short convalescence (4 to 6 weeks). Intraarticular injection of corticosteroids with or without hyaluronan can also improve the clinical signs, but surgery is preferable.

Larger Palmar Fragments of the Proximal Phalanx

Large fracture fragments often cause a more obvious lameness than the more common rounded fragments from the proximal palmar rim of the proximal phalanx. They must be distinguished from more palmar fragments that involve the insertions of the true distal sesamoidean ligaments because the latter are not equally good candidates for surgical removal. Very large, acute fractures of the palmar process of the proximal phalanx can be repaired with screws if recognized early (see Chapter 35). Large fragments occur in foals and weanlings, but clinical signs may abate quickly or be nonexistent. Lameness may be evident only when training or racing ensues. In foals, these fragments may be recognized radiologically if there is effusion, mild to moderate lameness, and obvious periarticular swelling. Lameness is seldom commensurate with fragment size. The lesions in foals are largely cartilaginous and can be followed over time as they develop as a separate center of ossification. These fractures should be differentiated from an avulsion fracture at the site of the medial (or, less commonly, the lateral) collateral ligament (see page 410).

Major Fractures of the Proximal Phalanx: Sagittal Fractures

The most common major fracture of the proximal phalanx is a sagittal crack propagating from the proximal sagittal groove. Horses with long sagittal, displaced sagittal, and comminuted fractures developing from an original fracture in the sagittal or frontal plane have obvious localizing signs of swelling and pain. Horses with shorter sagittal fractures may show more subtle signs. Degree of lameness with short, incomplete sagittal fractures is remarkably variable; some horses are almost unable to bear weight, whereas in others the lameness is barely perceptible (see Chapter 35). There is usually effusion of the fetlock joint, pain on manipulation (flexion and twisting), and pain with firm pressure over the middorsal aspect of the proximal phalanx. Sagittal fractures of the proximal aspect of the proximal phalanx are obvious radiologically if they extend more than a few centimeters from the joint surface, but a short, incomplete fracture is very frequently missed without good-quality radiographs. Although historically short incomplete fractures of the proximal aspect of the proximal phalanx were all thought to be dorsally located, recent information from MRI indicates that some short incomplete fractures are located midway between the dorsal and palmar cortices.²⁵ If a dorsal fracture is more than 10 days old, there is usually a definite periosteal change on the dorsal cortex seen on a lateromedial image just distal to the capsular attachments. Initially the change is very indistinct, but within a few more weeks, distinct periosteal new bone is obvious. Whenever proliferative change is seen in this area, the dorsopalmar images should be carefully evaluated for a sagittal fracture. Underexposure results in lesions being missed. However, a fracture midway between the dorsal and palmar cortices will not be associated with periosteal new bone formation, although in a dorsopalmar view it may be possible to detect thickening of the subchondral bone plate in the region of the sagittal groove compared with the contralateral limb. These fractures are more common in STBs than TBs but are also being recognized with increasing frequency in elite endurance horses and frequently involve more than one limb. These fractures also occur in other sports horses,^{8,35,36} and as in racehorses there is some evidence that preexisting pathological modeling of the bone may predate fracture. Even though these fractures are short and indistinct, they may cause surprisingly severe lameness. The clinician should always suspect such fractures because blocking followed by lunging, high-speed training, or pasture exercise may catastrophically propagate the fracture (Figure 36-10). For management and prognosis, see Chapter 35.

Dorsal Frontal Fractures of the Proximal Phalanx

See Chapters 35 and 42 for a discussion of dorsal frontal fractures of the proximal phalanx.

CONDITIONS OF THE PROXIMAL SESAMOID BONES

Sesamoiditis

Clinical Signs

The PSBs are an integral part of the suspensory apparatus and metacarpophalangeal articulation. They are susceptible

Fig. 36-10 • A subtle sagittal fracture of the proximal phalanx (*left*) that dehisced catastrophically following perineural analgesia (*right*).

to injury in all athletic horses, but particularly in those that perform at speed. Lameness resulting from sesamoiditis in sports horses is comparatively rare. Sesamoiditis is a clinically distinctive condition, although it is poorly characterized pathologically. There is usually pain with direct, firm palpation over the abaxial aspect of the affected PSB(s) and sometimes pain with fetlock flexion. Often, however, the lameness is manifest only after hard exercise. It is important to recognize that the radiological detection of an increased number and size of vascular channels may be an incidental finding. In a study to determine prevalence of radiological changes in the repository radiographs of 1162 TB yearlings selling in Kentucky, most yearlings (98%) had radiologically apparent vascular channels in the PSBs.³⁷ Irregular channels (>2 mm wide or with nonparallel sides) were more common (79%) than were regular vascular channels (56%). In a second study, race performance of these yearlings was studied. Yearlings with enthesophyte formation of the PSBs in the hindlimbs placed in a significantly smaller percentage of starts and earned significantly less money per start; however, the presence of abnormal vascular channels did not appear to influence performance.³⁸ However, the evidence is conflicting. In a study of 487 TB yearlings, those with vascular channels with nonparallel sides and more than 2 mm in width had a reduced number of race starts at 2 years of age and reduced earnings at 2 and 3 years of age compared with normal horses. Contour of the PSBs did not influence performance.³⁹ In a longitudinal radiological study of 71 2-year-old STBs examined at 3-monthly intervals over 1 year, 22% had no vascular channels and 55% had one or two vascular channels less than 1 mm in width, which did not change and did not influence performance. Three or more vascular channels less than 1 mm wide were seen in 13% of horses at the start of the study; the percentage decreased with time as some horses were removed from training. If lameness was observed, it was attributed to

suspensory desmitis or superficial digital flexor tendonitis. Seven horses (10%) had wide abnormally shaped vascular channels, all of which were considered to be associated with lameness during training.⁴⁰ In a radiological study of 753 STB trotters in Norway examined between 6 and 21 months of age, the presence of radiological abnormalities did not influence race earnings at 3 and 4 years of age.⁴¹

Diagnosis

The pain causing lameness is eliminated with perineural, but not intraarticular, analgesia. Radiological evidence of sesamoiditis involves four basic changes: marginal osteophytes, enthesophytes, enlarged vascular channels, and focal radiolucent defects (Figure 36-11). Marginal osteophytes occur at the proximal dorsal and distal dorsal extremities of the PSBs. Best seen on lateromedial images, these lesions represent later changes of generalized OA of the fetlock joint and usually can be considered a poor prognostic sign. Enthesophytes occur along the palmar aspect of the proximal half of the abaxial ridge of the PSB or the distal third of the bone at the sites of origin of the distal sesamoidean ligaments. These changes are frequently abaxial in location and therefore seen best on oblique images. Interpretation of vascular channels in the PSBs is always subjective. The direction of any linear radiolucency

is important to note; vascular channels have a radial orientation, whereas hairline fractures usually extend farther and are closer to transverse (parallel to the ground) (Figure 36-12).

True radiolucent changes that are not associated with the normal trabecular pattern or vascular channels may indicate infection (see Chapters 72 and 74). Such lesions may arise after known trauma to the region, especially a penetrating injury. Such lesions are usually extremely painful on palpation. A second important differential diagnosis is an avulsion fracture at the attachment of the palmar annular ligament (see Chapter 74). Radiolucent defects of hindlimb PSBs have also been described as a sequel to routine catheterization of the dorsal metatarsal artery for the measurement of intraoperative arterial blood pressure, with the development of severe lameness within 21 days of surgery.⁴² It was speculated that the lesions may be caused by ischemic necrosis or hematogenous spread of bacteria.

Nuclear scintigraphy is exceptionally useful for diagnosis of sesamoiditis and can identify early changes and help confirm whether a chronic radiological change is currently active. A complete series of scintigraphic images, including standing lateral, flexed lateral, and dorsal, can aid in exact localization of a lesion within a particular PSB.

Fig. 36-11 • Sesamoiditis lesions have a range of radiological pathology, including enlarged vascular channels, radiolucency, and enthesophytes.

Fig. 36-12 • Very subtle transverse lucencies in a proximal sesamoid bone can be an indication of an incomplete fracture (*left*). A midbody fracture (*right*) developed in a race a few weeks after the radiograph on the left was obtained.

Treatment

Treatment of horses with sesamoiditis is difficult and usually involves enforced rest and symptomatic treatment to counter inflammation and pain. Many racehorses with sesamoiditis are clinically helped considerably by postexercise icing and altered training regimens, such as swimming. It seems to be easier to manage older, proven racehorses with sesamoiditis by such methods than younger, unraced horses. Aspirin and isoxsuprine have been used, but there is no reliable evidence for efficacy. Shock wave therapy is probably the best current therapeutic option for horses with active sesamoiditis, although its efficacy and mechanisms of action are still debatable. Tiludronate has also been used for sesamoiditis and may have some rationale, but there is no good information about its efficacy.

Proximal Sesamoid Bone Fractures

There is anatomical variation in configuration of PSB fractures, substantially influencing clinical signs and outcome. Biaxial PSB fractures are a potentially catastrophic injury. A recent post mortem study indicated that TB racehorses with severe PSB fractures (75 of 121 fractures were transverse midbody fractures) had a higher exercise intensity in the previous 12 months compared with horses with other musculoskeletal injuries or other causes of death.⁴³

Clinical Signs

Because the PSBs are such important elements in the suspensory apparatus and support of the fetlock joint, fractures are usually associated with obvious clinical signs of heat, swelling, and pain with flexion or direct pressure, as well as an obvious weight-bearing lameness.

Diagnosis

Lameness caused by most PSB fractures is eliminated or greatly reduced by intraarticular or perineural analgesia. Apical, midbody, and basilar fractures of the PSBs usually are easy to diagnose radiologically with routine views. Abaxial fractures more frequently are missed and are best demonstrated by a lateral proximal-medial distal or medial proximal-lateral distal oblique image that is tangential to

the abaxial surface of the suspect PSB. This projection also is useful in determining whether the fracture is articular. Axial fractures usually are associated with displaced condylar fractures of the McIII or third metatarsal bone (MtIII). Diagnosis requires a well-penetrated dorsopalmar image that is well positioned. Even slight obliquity obscures the fracture line. Midbody fractures frequently have wedge-shaped, comminuted fragments present at the abaxial margins. They should not be confused with the overlapping lines of the palmar and dorsal cortices that occur because of fracture displacement and failure to obtain the radiograph directly through the fracture line.

Ultrasonography can be a valuable adjunct in evaluating PSB fractures because soft tissue attachments of the SL, intersesamoidean ligament, and distal sesamoidean ligaments can be simultaneously injured.

Apical Fractures

Apical fractures comprising less than 30% of the bone occur primarily in racehorses, but they can occur in all types of horses. Forelimb apical PSB fractures are much less common than hindlimb injuries in racing TBs^{44,45} and STBs.⁴⁶ In sports horses this injury is most common in event horses and show jumpers. These injuries are caused by a combination of bending and suspensory tensile forces. In young STBs the fracture is particularly common in the right hind lateral PSB. Horses with apical PSB fractures are usually mildly to moderately lame unless a concomitant SL injury is present. Although lameness in some horses has been managed successfully with rest alone, arthroscopic removal of the fractured fragment generally is recommended. Both prognosis and convalescent time depend on fragment size and presence of suspensory desmitis. Horses with small, apical fragments without major SL ligament injury can resume training within 4 to 6 weeks after surgery, especially if they were fit at the time of injury. Horses with large fragments usually associated with suspensory branch injury may need 6 to 12 months of convalescence and have a poor prognosis. The prognosis for return to racing was poorer for forelimb injuries than hindlimb injuries in racing TBs. In horses less than 2 years of age, 55% of 11

horses with a forelimb fracture raced after arthroscopic removal of the fragment, whereas 86% of 139 horses with a hindlimb injury raced.⁴⁴ In horses 2 years of age or more, 67% of 30 horses with a forelimb fracture returned to racing after surgery compared with 83% of 54 horses with hindlimb injury. In both age categories, fracture of a medial PSB significantly reduced the likelihood of return to racing.⁴⁵

Abaxial Fractures

Abaxial fractures are true avulsion injuries involving the insertion of the SL on the abaxial surface. Most involve a narrow rim of the articular surface and can be removed by an arthroscopic approach. Displaced fragments should be removed, whereas extremely large fragments can be repaired with 3.5-mm screws. Horses with nondisplaced fragments sometimes can be treated with rest. The prognosis depends on the size of the fragment and the concomitant suspensory compromise. In a study of 47 horses, predominantly TB and Quarter Horse racehorses and Western performance horses with an abaxial sesamoid fracture, 38 had a forelimb fracture, usually of the medial PSB. Nonracehorses had a better prognosis for return to full athletic function (6/6, 100%) after arthroscopic removal of the fracture compared with racehorses (25/35, 71%), with only 16 of 35 (46%) racing at the same class as preinjury.⁴⁷

Basilar Fractures

Basilar fractures of the PSBs are seen in all athletic horses and are treated according to configuration.^{48,49} Horses with smaller, wedge-shaped fragments that do not extend more than 50% to 75% of the dorsopalmar width of the PSB are clear candidates for surgical excision of the fragment (Figure 36-13). Such fragments do not heal with rest and

cause persistent lameness, presumably because of instability and incongruity at the articular surface. The prognosis with arthroscopic technique is at least 50% for return to athletic function because the distal sesamoidean ligaments are not disrupted. Horses are usually given 4 to 6 months of rest after removal of such fragments (3 months with very small pieces). Nonarticular fractures can be removed via an incision in the straight sesamoidean ligament, and 9 of 10 horses from a variety of disciplines returned to their intended use.⁵⁰

Horses with larger, basilar PSB fractures that extend to the palmar aspect of the bone have the poorest prognosis because fractures often are substantially displaced and involve a greater proportion of distal sesamoidean ligament origin (Figure 36-14). They also are more difficult to repair than midbody fractures because of the size and shape of the fracture. The prognosis for horses with large, displaced, or comminuted basilar PSB fractures is poor for return to any reasonable level of athletic activity.

Some horses with severe OA develop small basilar fractures. These fractures typically are more rounded, irregular, or multiply fragmented than acute chip fractures (Figure 36-15). Acute chip fractures have a sharply demarcated triangular shape. Horses with these degenerate basilar fractures are very poor candidates for any surgical treatment, and horses have a grave prognosis for return to athletic activity. Radiologically evident narrowing of the joint space between the PSB and the McIII (Figure 36-16) and the development of a radiological “waist” in the distal aspect of the McIII are associated signs of severe OA (Figure 36-17).

Midbody PSB Fractures

Midbody fractures of the PSB can occur in any horse, but they usually are seen in racehorses. In North American TBs, the medial PSBs of the forelimb are most commonly affected. In the STB, hind lateral midbody PSB fractures are

Fig. 36-13 • Lateromedial radiographic image of a metacarpophalangeal joint. There is a basilar sesamoid fracture (arrow). Small, triangular, basilar sesamoid fragments that do not involve the major distal sesamoidean ligaments are appropriate candidates for arthroscopic removal.

Fig. 36-14 • Flexed lateromedial radiographic image of a metacarpophalangeal joint. There is a large displaced basilar sesamoid fracture (arrow). Large basilar fractures are very difficult to successfully repair. There are extensive attachments of the distal sesamoidean ligaments; therefore the prognosis associated with surgical removal is poor.

Fig. 36-15 • Dorsomedial-palmarolateral oblique radiographic image of a metacarpophalangeal joint. There are fragments distal to the proximal sesamoid bone (*arrow*). Irregular, "crumbled" fragments from the base of the proximal sesamoid bone usually are seen in joints with moderate to severe osteoarthritis. Note also the modeling of the articular margins of the proximal phalanx.

Fig. 36-16 • Lateromedial radiographic image of a metacarpophalangeal joint. Note the loss of space between the proximal sesamoid bones (PSBs) and the third metacarpal bone (McIII) (*arrows*). Near-complete loss of joint space between the McIII and the PSBs can precede that between the distal aspect of the McIII and the proximal phalanx. Horses with this degree of cartilage damage are often candidates for euthanasia or arthrodesis.

most common. Numerous surgical techniques have been used to repair such fractures, including cast coaptation alone, bone grafting and casting, lag screws (distal to proximal or proximal to distal) with or without cancellous grafting, and hemicerclage wiring and graft.^{51,52} Regardless of the technique used, midbody PSB fractures are serious injuries, and horses require an extended period of rest after surgery. With surgery, 60% to 70% of horses with midbody fractures can return to athletic function, but most horses drop substantially in class. The owner or trainer should be advised that almost a year of convalescence is required for horses with such injuries.

Axial PSB Fractures

Axial PSB fractures are nearly always seen in combination with displaced lateral condylar fractures of the McIII or MtIII (Figure 36-18). They are recognized radiologically

Fig. 36-17 • Slightly oblique flexed lateromedial radiographic image of a metacarpophalangeal joint. Development of a "waist" around the proximal joint margin on the third metacarpal bone, both dorsally and palmarly (*white arrows*), is indicative of severe, chronic osteoarthritis. There is a pronounced defect of the distal palmar aspect of the third metacarpal bone (*black arrows*).

only on a dorsopalmar image, and it is difficult to determine fracture depth. Some fractures involve deep gouges in the articular surface, and most are avulsions by the inter-sesamoidean ligament. They usually are not treated specifically because of inaccessibility and the likelihood that the condylar fracture and overall joint damage will limit return to function. Recognition of an axial PSB fracture is important primarily as an indicator of more severe trauma to the joint and a poorer prognosis. The prognosis for a horse returning to race after this injury is extremely poor.⁵³ Early metacarpophalangeal arthrodesis should be seriously considered in horses with a displaced axial sesamoid fracture.

Intraarticular Fragmentation Associated with Suspensory Branch Injury

The distal dorsal aspect of the branches of the SL are sub-synovial and therefore intimately associated with the fetlock joint. Occasionally in association with injury of the medial or lateral branch of a SL, there is associated distention of the fetlock joint capsule; in a flexed lateromedial radiographic image, several small osseous fractures can be identified on the proximal dorsal aspect of the ipsilateral PSB. Such fracture fragments must be surgically removed for a successful outcome. Prognosis depends on the severity of the suspensory branch injury.

Intersesamoidean Ligament Injury

Intersesamoidean ligamentous injury without fracture is difficult to diagnose unless it is accompanied by radiolucency along the axial aspect of one or both PSBs (Figure 36-19). Affected horses often are extremely lame even at a walk. Scintigraphy frequently identifies an area of intense, focal IRU. The intersesamoidean ligament also can be

Fig. 36-18 • Displaced lateral condylar fracture of the third metacarpal bone with a nondisplaced axial fracture (arrows) of the lateral PSB (left). In horses with very badly displaced lateral condylar fractures, the axial fragment of the PSB can become completely avulsed (right). Clinicians should look for axial PSB fractures in every horse with a displaced lateral condylar fracture. This type of fracture is associated with a very poor prognosis for return to racing.

Fig. 36-19 • A good-quality dorsopalmar radiographic image is necessary to diagnose a radiolucent defect involving the axial margin of the proximal sesamoid bone (arrows).

evaluated ultrasonographically to a limited extent. The ligamentous lesion may be visible and debrided arthroscopically, but it is not known if this alters the outcome. Horses generally are treated with support bandages and stall rest for several months. The prognosis for return to high-level athletic activity appears to be guarded, especially with conservative management, but a large series of horses has not been reviewed. Lameness resolved in eight horses treated by surgical debridement.⁵⁵ Differential diagnosis for radiolucent lesions in the intersesamoid region also includes osteomyelitis.³⁷ If an infection is the cause of the bone loss, horses typically have more obvious localizing signs, such as joint capsule and digital flexor tendon sheath distention, and the prognosis is poor.

PSB Fractures in Young Foals

PSB fractures in young foals (apical, abaxial, midbody, and basilar) can occur at pasture and appear to be

underdiagnosed because clinical signs are surprisingly subtle and foals often are not thoroughly examined for mild lameness. Because most fractures involve only one PSB and the suspensory apparatus is still functional, severe lameness does not develop. Clinicians should look for subtle clinical signs of fetlock region swelling, pain with flexion, and pain with pressure over the PSBs in any foal with mild to moderate lameness. Several bones can be affected. Signs often abate quickly, especially in young foals (<2 months of age), in which these fractures are most common. Good-quality radiographs are essential because the fractured apical, basilar, or abaxial fragments are often poorly mineralized. Unlike in older horses, PSB fractures in foals frequently progress to form a bony union (see Figures 128-6 and 128-7). If the fragments have any displacement, however, an enlarged PSB can result. These oversized PSBs often are diagnosed in yearlings or 2-year-olds on prepurchase or presale radiographs. Surprisingly, enlargement of the fetlock joint is usually difficult to detect. Although some horses have raced successfully with enlarged PSBs, this abnormality can be a source of lameness as the horse proceeds in training.

PSB fractures in foals are essentially a management problem. Avoidance of situations in which a young, weak foal has to chase its dam around a large pasture to the point of exhaustion can prevent many fractures. It is essential to slowly return foals back to pasture if they have been stall confined for any reason. Early recognition of lameness in foals can allow diagnosis before the fragments become markedly displaced. Early diagnosis improves prognosis considerably because minimally displaced fractures nearly always heal completely with rest alone. Uncontrolled exercise by the foal must be avoided because the degree of displacement dictates the eventual PSB deformity. Surgical treatment of foal PSB fractures is primarily indicated in markedly displaced fractures close to the midbody of the bone. A suturing technique with high-tensile-strength flexible fiber is probably the best current option.

FRACTURES OF THE THIRD METACARPAL BONE

Condylar Fractures

Clinical Signs

The most important fracture of the fetlock joint is that involving the condyles of the McIII. They occur almost exclusively in racehorses and elite endurance horses, usually only when horses are running at racing speeds. This is also an occasional injury in event horses. Because the fractures involve a major weight-bearing surface, most horses are overtly lame, with clear localizing signs of pain and swelling. Most are very positive to any manipulation of the fetlock. Degree of lameness often does not directly correlate with the degree of displacement. Many horses with incomplete, acute fractures are lammer than one with a clearly displaced, complete fracture. This is particularly true with incomplete medial fractures. Although it appears that many horses that develop condylar fractures have preexisting subchondral damage of the distal palmar aspect of the condyle,^{27,56} the majority do not have a strong history of previous fetlock lameness (see Chapter 42 for fractures of the MtIII).

Diagnosis

Radiological diagnosis is not difficult in most horses. A dorsopalmar image should be centered over the condyle and the x-ray beam directed 15 to 20 degrees downward. If the beam is too horizontal, the PSBs may obscure the distal articular surface of the McIII. Lesions may be missed if images are underexposed. The most common fractures involve the lateral condyle and clearly propagate toward the lateral cortex. Some extend only 1 to 2 cm proximally from the joint surface, and these can be particularly difficult to see without good-quality radiographs. Lateral condylar fractures rarely spiral or extend into the middiaphysis. Medial condylar fractures, however, usually extend up the diaphysis in a spiraling fashion or have an occult Y-shaped configuration at the middiaphysis. *It is essential to remember the difference between lateral and medial fractures.* Horses with

medial condylar fractures *must* have a complete, high-quality set of radiographs that encompass the entire length of the McIII in an attempt to identify fracture configuration. Most importantly, the owner or trainer must be informed immediately of the substantial risk associated with medial fractures, especially those involving a hindlimb.

The prognosis for horses with displaced, lateral condylar fractures, regardless of treatment, is much poorer for return to function compared with those with nondisplaced fractures. This is almost certainly the result of a combination of preexisting disease of the fetlock joint and the magnitude of damage done to the joint when the fracture occurs. Accurate prognosis requires radiographic examination of the palmar distal aspect of the McIII. The radiographer should slightly flex the fetlock and use a horizontal beam to obtain a dorsopalmar image (Figure 36-20). This helps to define comminution of the condyle along the fracture margin, as well as subchondral radiolucent defects that may have preceded the fracture.

Most horses with condylar fractures are best treated with lag screws. Nondisplaced or minimally displaced fractures can be repaired through stab incisions alone, but arthroscopic evaluation of the joint should allow a more accurate assessment of the prognosis. Displaced fractures require accurate reduction of the distal articular surface, so they must be reduced under arthroscopic guidance or through an open incision. Horses with medial condylar fractures should undergo surgery with extreme caution because catastrophic failure in the middiaphysis can occur during recovery from general anesthesia or even several days to weeks after repair (see Chapter 42). Horses with spiral fractures extending the length of the diaphysis may be successfully repaired with carefully positioned lag screws alone, but those with medial fractures that disappear in the middiaphysis should be repaired with a bone plate combined with lag screws across the condyle. Most complications of condylar fractures occur because of a failure to recognize potential problems before surgery. Even if certain complications cannot be entirely avoided, forewarning the owner of the risks is advisable.

Fig. 36-20 • A standard dorsopalmar image of a lateral condylar fracture obtained at a 10- to 15-degree proximal to distal obliquity will separate the distal aspect of the third metacarpal bone from the base of the proximal sesamoid bones (*left*), but a dorsopalmar image obtained with the fetlock slightly flexed is needed to silhouette the distal palmar margin of the bone where comminution typically occurs (*right*).

Other fractures of the distal third of the McIII bone are discussed in Chapter 37.

OSTEOCHONDROSIS

Sagittal Ridge of the Third Metacarpal Bone

The most common site of osteochondrosis in the metacarpophalangeal joint (excluding proximal palmar lesions) is the dorsal sagittal ridge of the McIII/MtIII (Figure 36-21).⁵⁷ These lesions often are clinically silent, but mild to moderate effusion and lameness may be noted. They are often diagnosed in weanlings or on yearling presale radiographs. They are best seen on a dorsopalmar image or a slightly underexposed flexed lateromedial image. If no fragment is obvious and clinical signs are minimal, it is advisable to rest the horse for a couple of months because some healing may occur, especially in younger horses. Arthroscopic debridement is an option, but the resulting bony defect will remain evident, and thus the likelihood of a rewarding sale price is lessened. If the lesion does not fill in

radiologically by the spring of its yearling year, arthroscopic evaluation may be suggested. A completely conservative (i.e., nonsurgical) approach is justified if the clinical signs are minimal. The prognosis likely depends on the size of the lesion. Horses with lesions more proximal on the sagittal ridge may have a better prognosis than those closer to its distal aspect.

In older horses, traumatic chip fractures may occur on the distal aspect of the sagittal ridge in a similar location to that of typical osteochondrosis (Figure 36-22). This injury may occur in jumpers striking an obstacle with the fetlock joint in a palmarly flexed position. These fragments usually are unstable and should be arthroscopically removed. The prognosis is favorable if the fragment is fairly small.

Osseous Cystlike Lesions of the Third Metacarpal Bone

Osseous cystlike lesions of the distal aspect of the McIII/MtIII occur on the weight-bearing surface of the condyle and may be a manifestation of osteochondrosis. Most

Fig. 36-21 • Dorsopalmar (*left*) and flexed lateromedial (*right*) images of a metacarpophalangeal joint. Note the radiolucent defect (*arrow*) in the sagittal image in the dorsopalmar image and the smoothly outlined defect in the dorsal aspect of the sagittal ridge (*arrows*) of the third metacarpal bone in the lateromedial image.

Fig. 36-22 • In adult horses some fragments involving the dorsal sagittal ridge of the third metacarpal bone are caused by direct trauma. Both of these horses struck fixed objects with the affected fetlock in flexion.

occur in the medial condyle and are diagnosed in yearlings or early in training as a 2-year-old. The lesions are easy to recognize radiologically, and horses have obvious lameness exacerbated by lower limb flexion. Perineural analgesia and scintigraphy also localize the problem. Surgical debridement has been the typical treatment, and the reported results are unexpectedly favorable.⁵⁸

COLLATERAL LIGAMENT INJURY

The fetlock joint has strong anatomical constraints, and the equine limb and gait have a strongly sagittal orientation; therefore mediolateral instability is relatively uncommon except after severe trauma (e.g., foot in a hole or lower limb in a gate or fence). Mild forms of collateral desmitis are suspected in horses with pain on fetlock manipulation, focal pain, and swelling over the affected ligament or lameness exacerbated with valgus or varus stress. The diagnosis is confirmed by ultrasonographic examination. However, localizing clinical signs may be absent, and if a horse has pain causing lameness localized to the fetlock region by perineural analgesia and little response to intraarticular analgesia, then the collateral ligaments should be included in a routine ultrasonographic assessment of the periarticular structures. It must be borne in mind that the deep and superficial components of each collateral ligament cannot be evaluated simultaneously because of their different fiber orientations. Radiographs usually are not helpful unless there is an avulsion fracture or lack of congruency of the joint surfaces. However, radiographic examination is important if there is joint laxity because there may be concurrent intraarticular fragments. Joint instability is most likely to be demonstrated on non-weight-bearing, valgus or varus stressed dorsopalmar (plantar) radiographs.

Treatment of horses with collateral ligament injury usually consists of rest and adequate external coaptation. The fetlock is an inherently stable joint in the sagittal plane; thus minimal support is necessary unless the injury is severe. If the joint is very unstable, a cast extending to the proximal metacarpal region is maintained for 4 to 6 weeks. If the injury is not overtly unstable, a single polyvinyl chloride pipe splint applied on the side ipsilateral to

the collateral injury should be adequate. The duration of rest should be based on clinical soundness, palpable stability, and the ultrasonographic appearance of the ligamentous tissues (see Chapter 17). Shock wave therapy for insertional desmopathies may be beneficial, but firm data are still unavailable. Stem cells, acellular matrices, and platelet-rich plasma are also empirically used. Eight of 16 horses with rupture of a collateral ligament of the metacarpophalangeal or metatarsophalangeal joint returned to pleasure riding after casting for a mean of 71 days.⁵⁹

Collateral ligament avulsion injuries involving the insertion on the proximal phalanx are perhaps the most commonly recognized fetlock collateral ligament injury. These may easily be mistaken for the more common dorsal chip fractures on oblique views, but careful scrutiny reveals that the fragment is too far abaxial for a typical chip fracture (Figure 36-23). If a fracture is seen abaxial to the apex of the dorsal eminences of the proximal phalanx, the fragment is almost certainly not going to be from the typical articular margin location. In addition, the fracture can also usually be seen in an abaxial position on a dorsopalmar (dorsoplantar) image. These fragments often involve a portion of the articular margin and cause lameness. Arthroscopic removal should be performed, but it can be difficult because of the limited space on the medial or lateral aspects. The arthroscope portal should be dorso-proximal on the same side as the lesion. The instrument portal should be just dorsal to the edge of the collateral ligament. The fragments may be tightly attached along the abaxial margin, and an arthroscopic scalpel or other sharp dissection tool may be needed to separate them. The most important issue with these fragments is that the clinician accurately discriminates between them and a more typical articular margin fracture; otherwise, the surgical procedure may be very frustrating.

TRAUMATIC DISRUPTION OF THE SUSPENSORY APPARATUS

See Chapter 104 for a discussion of traumatic disruption of the suspensory apparatus and associated catastrophic injuries.

Fig. 36-23 • Collateral ligament avulsions from the proximal phalanx are usually visible on the dorsopalmar (*left*) and the oblique (*right*) radiographic images. On the oblique image, these fragments appear a long way from the third metacarpal bone and that distinguishes them from a typical dorsal proximal phalanx chip fracture.

Chapter 37

The Metacarpal Region

Sue J. Dyson

ANATOMY

This chapter discusses the examination and diagnosis of injuries to the metacarpal region of the horse. The detailed anatomy of the deep digital flexor tendon (DDFT) (see Chapter 70), the accessory ligament of the deep digital flexor tendon (ALDDFT) (see Chapter 71), the superficial digital flexor tendon (SDFT) (see Chapter 69), and the third interosseous muscle or suspensory ligament (SL) (see Chapter 72) is discussed elsewhere.

In the metacarpal region the interosseous ligaments attach the second (McII) and fourth (McIV) metacarpal bones to the third metacarpal bone (McIII). These ligaments ossify to a variable extent during skeletal maturation. Fibrous bands extend from the distal aspect of the McII and McIV to the medial and lateral proximal sesamoid bones (PSBs).

The proximal aspect of the third interosseous muscle or SL attaches to the proximal palmar aspect of the McIII and the palmar carpal ligament and lies between the McII and McIV. Large exostoses on the axial aspect of the McII or the McIV have the potential to impinge on the abaxial border of the SL. The carpal sheath (see Chapter 75) extends through the proximal third of the metacarpal region. The amount of fluid in the carpal sheath varies between horses but is usually bilaterally symmetrical.

The digital flexor tendon sheath (DFTS) envelops the SDFT and DDFT from the distal third of the metacarpal region to the middle of the middle phalanx. Palmar to the metacarpophalangeal joint, the sheath passes through the inelastic canal created by the palmar annular ligament (PAL), the palmar fibrocartilaginous surfaces of the PSBs, and the intersemoidean ligament. Within the DFTS, proximal to the sesamoidean canal, the SDFT forms a ring (the manica flexoria) around the DDFT. In the palmar mid-sagittal plane, a synovial reflection, the vincula, attaches the SDFT to the DFTS wall. Proximal to the manica flexoria, the DDFT is attached medially and laterally by mesotendon to the DFTS wall. The lateral mesotendon is more substantial and extends farther distally.

The palmar and palmar metacarpal nerves innervate the palmar metacarpal region. The SL is innervated by the medial and lateral palmar metacarpal nerves, branches of the deep branch of the lateral palmar nerve. This nerve receives contributions from the ulnar and median nerves. The medial palmar metacarpal nerve has fibers only from the median nerve, whereas the lateral palmar metacarpal nerve has fibers from the ulnar and median nerves.¹ The SDFT and DDFT are innervated by the palmar nerves.²

In the proximal metacarpal region, the palmar nerves lie beneath relatively thick fascia, whereas farther distally they are more superficial. In the proximal 5 cm of the

metacarpal region, the palmar metacarpal nerves and the distal palmar outpouching of the carpometacarpal joint capsule are in close proximity.

DIAGNOSIS

Clinical Examination

The metacarpal region should be examined visually from all angles to identify any changes in contour caused by swelling. If the limb is hairy, subtle swellings may easily be missed, especially in heavier breeds of horses, and if injury to the metacarpal region is suspected, then clipping the hair to facilitate examination can be useful. Palpation of the metacarpal region should be performed systematically with the limb bearing weight and with the limb semiflexed. With the limb bearing weight, the contour of the dorsal and palmar aspects of the limb should be straight. Distention of the medial palmar vein may reflect local inflammation. The size of the SL and its branches is assessed by running both thumbs down the dorsal and palmar borders from proximally to distally, medially, and laterally; they should remain equidistant. With the limb lifted, the margins of each of the SDFT, DDFT, ALDDFT, and SL should be carefully palpated to detect rounding of the margins, enlargement, or change in texture. Each structure should be squeezed, starting proximally and working distally, gently at first and then with increasing pressure to determine whether pain can be elicited. Careful comparison should be made with the contralateral limb, bearing in mind that lesions may be present bilaterally. Assess the response in light of the horse's temperament and the recent work history. Abnormal stiffness of a structure may reflect previous injury. It is necessary to roll away the digital flexor tendons and compress the SL against the palmar aspect of the McIII to assess the most proximal part of the SL.

The axial and palmar margins of the McII and McIV should be palpated to identify any new bone formation (a splint) and to determine whether applied pressure causes pain. It is also important to assess whether the axial margin of the splint is clearly demarcated from the SL. Firm pressure should be applied to the dorsal aspects of the McIII to identify pain.

Local Analgesic Techniques

When local analgesic techniques are performed in the metacarpal region, it is important to recognize the potential for local anesthetic solution to diffuse proximally from the site of injection and thereby desensitize structures farther proximally, partially, or completely. Minimum volumes of local anesthetic solution should be used (maximum 2 mL/site and less in ponies) to minimize the risks of misinterpretation. The horse should stand still after injection before reassessment of the gait and should be reevaluated no more than 10 minutes after injection. Even then, false-positive results may be seen.

The metacarpal region seems particularly prone to development of swelling at the site of injection, which potentially may be permanent. The limb should be thoroughly scrubbed with chlorhexidine before injection to minimize the risk of adverse reaction and because of the potential for inadvertent injection into a synovial cavity

(the DFTS, carpal sheath, or carpometacarpal joint capsule). The use of nonirritating local anesthetic solution (mepivacaine) is strongly recommended. It is also suggested that a stable bandage be applied to the limb for about 18 hours after injection.

Perineural analgesia of the palmar nerves at the level of the base of the PSBs desensitizes the foot and pastern regions, but in some horses it may also alleviate pain from the metacarpophalangeal joint, the proximal phalanx, PAL, SL branches, and DFTS. In horses with pain arising from the metacarpal region, lameness often appears paradoxically worse after palmar (abaxial sesamoid) nerve blocks, especially with proximal suspensory desmitis. Complete desensitization of the distal third of the metacarpal region requires perineural analgesia of the palmar nerves at the junction of the proximal two thirds and distal one third of the metacarpal region and the palmar metacarpal nerves distal to the distal aspect of the McII and McIV, the so-called low palmar or four-point block. Care should be taken to avoid inadvertent injection into the DFTS, which can occur when performing the palmar block despite no synovial fluid appearing in the needle hub. Proximal diffusion may result in partial alleviation of pain from the body of the SL in association with ultrasonographic evidence of proximal suspensory desmitis. If a unilateral lesion is suspected, the block may be performed medially or laterally alone.

Desensitization of one specific PSB can be achieved by blocking the sesamoidean nerve by introducing a needle between the insertion of the SL and the dorsal aspect of the abaxial surface of the sesamoid bone. The needle is directed toward the apex of the bone, and 0.5 mL of local anesthetic solution is injected.³

Elimination of pain from the entire metacarpal region requires blocking the palmar nerves immediately distal to the carpus and the deep branch of the ulnar nerve (and thus the palmar metacarpal nerves). However, often it is useful to be more specific and desensitize the deep structures (the palmar aspect of the McIII and the SL) or the more superficial structures (SDFT, DDFT, and ALDDFT). Perineural analgesia of the deep branch of the lateral palmar nerve or of the palmar metacarpal nerves by subcarpal injection should theoretically not abolish pain from the fetlock or more distal aspect of the limb, but this does sometimes occur. It is therefore important to perform the low 4-point block first. Blocking the palmar metacarpal nerves immediately distal to the carpus runs the risk of inadvertent injection into the distopalmar outpouchings of the carpometacarpal joint or spread of the local anesthetic solution by diffusion. Theoretically the risk of failure to desensitize the most proximal aspect of the SL exists, but diffusion of local anesthetic solution usually removes pain; false-negative results sometimes occur. The response should be compared with that following intraarticular analgesia of the middle carpal joint. Occasionally subcarpal analgesia of the palmar metacarpal nerves relieves pain associated with a primary middle carpal joint lesion better than intraarticular analgesia. Intraarticular analgesia of the middle carpal joint may relieve pain associated with proximal suspensory desmitis or a palmar cortical fatigue fracture of the McIII.

Perineural analgesia of the lateral palmar nerve from the lateral⁴ or medial⁵ approach entails less risk of affecting

the middle carpal joint, but it does not eliminate it totally. The potential to remove pain from the lateral aspect of the more distal part of the limb also exists. From the lateral approach there is also a substantial risk of desensitization of the carpal sheath. This block can be particularly useful in a difficult horse, which is easier to inject with the limb bearing weight rather than semiflexed.

Theoretically, blocking the ulnar nerve should not completely remove pain associated with the proximal aspect of the SL or the proximal palmar aspect of the McIII because of the contribution of fibers from the median nerve to the medial and lateral palmar metacarpal nerves. However, in practice it generally does. The ulnar nerve block can be particularly useful to differentiate proximal metacarpal region pain from carpal pain in horses with an equivocal response to subcarpal analgesia; however, occasionally carpal pain is reduced.

Perineural analgesia of the palmar nerves (2 mL/site) should not desensitize the deeper structures (the McIII, SL) but should alleviate pain from the more superficial structures (SDFT, DDFT, and ALDDFT). Local infiltration around a painful exostosis of the McII or the McIV seems to be the most effective way of determining whether pain from the exostosis is contributing to the lameness observed. However, occasionally perineural analgesia proximal to the painful splint exostosis is necessary to abolish pain.

Intraarticular analgesia of the DFTS usually results in improvement in lameness associated with pain from within the sheath, but a better response is frequently seen after perineural analgesia of the palmar and palmar metacarpal nerves. Injection into the DFTS is most easily performed on the palmar midline of the pastern region, distal to the proximal digital annular ligament. The likelihood of inducing iatrogenic hemorrhage at this site is small, and retrieval of synovial fluid usually is easier than from the DFTS proximal to the PAL. If distention of the DFTS is only mild, compression of the proximal part of the sheath by an assistant to increase distention in the palmar pouch in the pastern can be helpful. Injection into the carpal sheath is usually only indicated if the sheath is distended (see Chapter 75).

IMAGING

Radiography and Radiology

Radiographic examination of the metacarpal region is usually tailored to each particular horse concerning the images required and the exposure factors used. With localized periosteal new bone, often finely coned-down images and use of soft exposures (low kilovolts [peak]) are required to demonstrate the lesion best. Several similar images varying slightly in obliquity may be required rather than a full series of dorsopalmar, lateromedial, dorsolateral-palmaromedial oblique, and palmarolateral-dorsomedial oblique images. Therefore a flexible approach must be used, depending on the initial clinical signs. Little soft tissue covers the metacarpal region; therefore a grid is not required. A high-definition screen with slow-speed film provides the best detail, although this may not be necessary with digital or computed radiography. Diffuse swelling in the metacarpal region makes images appear flatter, lacking contrast. Exposure factors may need to be increased slightly.

Superimposition of the McII and McIV over the McIII can create confusing radiolucent Mach lines (see page 174). The nutrient canal in the McII and McIV varies in prominence⁶ and should not be confused as a fracture. Ossification varies between the McII and McIV and the McIII in normal horses.

Ultrasonography

Ultrasonographic examination of the metacarpal region is discussed in detail elsewhere (see Chapters 16 and 69 to 72). In large, cob-type horses, the skin and underlying subcutaneous tissues in the metacarpal region may be thick, making it difficult to obtain high-resolution images. Dense stubble may persist after fine clipping of the hair coat, making it difficult to maintain good contact. Deep skin folds may further complicate the issue. For these horses it may be necessary to amplify the power and gain controls of the ultrasound machine and increase the focal depth of the transducer. Image quality may be enhanced by application of copious amounts of the ultrasound coupling gel to the skin for at least 15 minutes before imaging.

Nuclear Scintigraphy

Blood pool (soft tissue phase) and bone phase (delayed) images of the metacarpal region are particularly useful in horses in which pain has been localized to the metacarpal region but in which no clinically significant radiological or ultrasonographic abnormalities have been identified. Many exostoses involving the McII and the McIV, although clinically inactive, are associated with moderately increased radiopharmaceutical uptake (IRU). Clinically silent enostosis-like lesions also may have IRU.

Magnetic Resonance Imaging

Both high-field⁷⁻⁹ and low-field¹⁰ magnetic resonance imaging (MRI) have the potential to identify both osseous and soft tissue injuries that are not detectable using conventional imaging modalities.

DIFFERENTIAL DIAGNOSIS

Bucked or Sore Shins and Saucer (Dorsal Cortical) Fractures of the Third Metacarpal Bone

See Chapter 102 for a discussion of bucked shins and dorsal cortical (saucer) fractures of the McIII.

Medial and Lateral Condylar Fractures of the Third Metacarpal Bone

See Chapter 36 for a discussion of medial and lateral condylar fractures of the McIII (see page 408).

Incomplete, Longitudinal Palmar Cortical Fatigue Fractures of the Third Metacarpal Bone and Stress Reactions

Incomplete palmar cortical fatigue fractures of the McIII are relatively common and almost invariably involve the medial aspect of the bone,¹¹⁻¹⁴ may involve the metaphyseal and proximal diaphyseal region, and sometimes extend proximally to involve the carpometacarpal joint. They are believed to be fatigue or stress fractures because increased

radiopacity may be present radiologically when lameness is first recognized, indicating previous bony reaction.

These fractures occur most commonly in young horses, but they also occur in skeletally mature horses. In some horses, a recent increase in work intensity can be identified, which may be a predisposing factor. These fractures have been identified in a variety of racehorses sports horses, including horses used for flat and harness racing, National Hunt racing, and point-to-point racing, dressage, eventing, and endurance riding.

Clinical Signs

Lameness usually is sudden in onset and may be unilateral or bilateral. In some horses with bilateral injury, lameness is insidious in onset, and the horse has loss of forelimb action. Lameness varies from moderate to severe and tends to be worst on hard ground, and often the horse appears to become lamer the farther it trots. After the horse turns at the walk, the lameness then improves and again deteriorates as the horse trots. If the lameness is bilateral and similar in degree in each limb, the horse moves with a short striding, stilted gait.

Usually no localizing clinical signs suggest the source of pain. Often the horse does not react to palpation of the proximopalmar aspect of the McIII, unless the injury is acute.

Diagnosis

Lameness is substantially improved or alleviated by palmar metacarpal (subcarpal) nerve blocks or perineural analgesia of the deep branch of the lateral palmar nerve. Lameness may be improved in some horses by intraarticular analgesia of the middle carpal joint.

Dorsopalmar radiographic images of the proximal metacarpal region may reveal increased radiopacity of the proximal medial aspect of the McIII, with or without a longitudinal radiolucent line extending a variable distance proximodistally (Figure 37-1). If present, the radiolucent line is invariably located medial to the axis of the McIII. Several slightly oblique dorsopalmar images may facilitate identification of a fracture. Generally no radiological abnormality is detectable in other images, although very occasionally periosteal callus is seen on the palmar aspect of the McIII in a lateromedial image. In some horses, no detectable radiological abnormality exists at any stage.

Diagnostic ultrasonography usually reveals no detectable abnormality. Rarely a defect in the palmar cortex of the McIII can be identified. Nuclear scintigraphic images usually demonstrate moderate to intense IRU in the proximal palmar aspect of the McIII in dorsal and lateral bone phase images (Figure 37-2). Early radiopharmaceutical uptake in the proximal palmar aspect of the McIII may also be evident in pool phase images. This pattern of uptake is indistinguishable from that associated with an avulsion fracture of the McIII at the attachment of the SL. It is not known whether horses without radiological change, but with scintigraphic evidence of an increased bone modeling in the proximal aspect of the McIII, would develop a radiologically evident incomplete palmar cortical fracture of the McIII if the horses were kept in work, or whether this is a different manifestation of the response of bone to exercise.

MRI in a small number of Thoroughbred (TB) racehorses with no detectable radiological abnormality revealed

Fig. 37-1 • A, Dorsopalmar radiographic image of the right third metacarpal bone of a 6-year-old Thoroughbred hurdler with moderate right forelimb lameness recognized 7 days previously and alleviated by subcarpal analgesia of the palmar metacarpal nerves. Medial is to the left. The medial aspect of the metaphyseal and proximal diaphyseal regions of the third metacarpal bone has increased radiopacity. A poorly defined longitudinal radiolucent line (arrows) represents an incomplete longitudinal palmar cortical fatigue fracture. **B,** Dorsopalmar radiographic image of the right proximal metacarpal region of a 6-year-old Arabian endurance horse with a moderate right forelimb lameness of 3 weeks' duration. Lameness was alleviated by perineural analgesia of the deep branch of the lateral palmar nerve. Well-defined increased radiopacity immediately proximal to the nutrient foramen surrounds a longitudinal radiolucent line in the third metacarpal bone (arrows). **C,** The same horse as in **B** after 4 weeks of box rest. The radiolucent line extends further proximally (arrows).

diffuse areas of reduced signal intensity in the proximal palmar aspect of the McIII in T1 gradient echo (GRE) images and increased signal intensity in fat-suppressed and T2-weighted GRE images (surrounded by a hypointense rim in T2-weighted images, the result of a fluid-fat cancellation artefact), consistent with bone trauma.¹⁵ In some horses a cortical defect consistent with a fracture was identified, usually medially. The clinical characteristics of the lameness in these horses were not described and scintigraphy was not performed. It is not clear whether these injuries are stress-related bone injuries that reflect a continuum with palmar cortical fatigue fractures. Similar abnormalities have also been seen in endurance and other

sports horses, in association with IRU, and similar lameness characteristics of those described for palmar cortical fatigue fractures.¹⁰ Generally the entire palmar aspect of the McIII is involved, sometimes accompanied by signal alterations in the McII or the McIV, unlike the palmar cortical stress fractures described above in which radiological abnormalities are usually restricted to the medial aspect of the McIII. However, the MR signal alterations were usually most extensive medially.

Treatment

Most horses respond well to rest, with box rest for 1 month and then box rest and controlled walking exercise for

Fig. 37-2 • Dorsal (A) and lateral (B) scintigraphic images of the carpal and proximal metacarpal regions of the forelimbs of an 8-year-old advanced event horse with acute-onset moderate left forelimb lameness of 3 weeks' duration. The left forelimb is on the right in the dorsal image (A). Lameness was alleviated by subcarpal analgesia of the palmar metacarpal nerves. The character of the lameness was typical of a palmar cortical fatigue fracture, but no radiological or ultrasonographic abnormality was detected. Intense focal increased radiopharmaceutical uptake in the proximal, medial, palmar aspect of the third metacarpal bone is compatible with a stress or fatigue fracture.

another 2 months. Horses are then able to slowly and progressively resume normal work. The incidence of recurrent injury is small. Every attempt should be made to identify any problem with the previous training program that may have predisposed the horse to injury.

Midshaft Fractures of the Third Metacarpal Bone

See page 502 for a discussion of midshaft fractures of the McIII.

Transverse Stress Fractures of the Distal Metaphyseal Region of the Third Metacarpal Region

Transverse stress fractures of the distal metaphyseal region of the McIII are relatively uncommon.¹⁶ I have seen this fracture in horses of 4 to 7 years of age in the first season of racing over fences, in young polo ponies, and in pleasure horses that have galloped on the beach. These fractures are believed to be stress fractures because endosteal and periosteal callus has usually been identified radiologically at the first recognition of the lameness. Acute fractures have also been identified in young TB flat racehorses, sometimes only in light work.

Clinical Signs

In young immature TB racehorses there is usually acute-onset severe lameness unassociated with work. There is rapid development of swelling in the distal third of the metacarpal region on the palmar, palmaromedial, or palmarolateral aspects, which is exquisitely painful on palpation and may mimic cellulitis. Radiographs are usually negative initially, but within 7 to 10 days a transverse

radiopaque line becomes apparent across the distal metaphyseal region and ill-defined periosteal new bone proximally and distally, resulting in distortion of the distal aspect of the McII or the McIV. In some horses, a radiolucent fracture line may eventually be identified. Lameness takes several months to resolve, and there is slow remodeling of the periosteal callus.

In older horses, lameness is usually acute in onset after fast work, is moderate to severe, and may be unilateral or bilateral. Lameness may improve rapidly with the horse appearing sound within a few days. In horses with long-standing lameness, a change in contour of the distal dorsal aspect of the McIII is visible and is associated with periosteal callus formation. In these horses, pain may be elicited by firm pressure applied to the distal dorsal or palmar aspects of the McIII. Twisting the McIII may also induce pain. However, horses with acute lameness may have no localizing signs.

Diagnosis

If lameness persists, local analgesic techniques can be used to isolate the pain, but in some horses this is not possible because of the rapid resolution of lameness, unless the horse is maintained in full work. Lameness is eliminated by palmar (midcannon) and palmar metacarpal (distal to the button of the McII and the McIV) nerve blocks, but it is not influenced by intraarticular analgesia of the metacarpophalangeal joint.

Dorsopalmar, dorsolateral-palmaromedial oblique, dorsomedial-palmarolateral oblique, and lateromedial radiographic images of the fetlock region should be obtained. Flexed lateromedial images are preferable because this technique lifts the PSBs away from the palmar cortex of the

Fig. 37-3 • Dorsolateral-palmaromedial oblique radiographic images of fetlock region of a 3-year-old Thoroughbred flat racehorse obtained 4 days (**A**) and 33 days (**B**) after onset of severe lameness, associated with soft tissue swelling in the distal metacarpal region. There is a transverse stress fracture of the distal metaphyseal region of the third metacarpal bone (*black arrows*) with periosteal callus (*white arrows*). Note the distortion of the distal aspect of the fourth metacarpal bone.

McIII, allowing better evaluation. Radiological abnormalities may include a horizontal fracture line and endosteal and periosteal callus (Figure 37-3). Some horses, in particular those with acute lameness, may have no detectable abnormality.

Nuclear scintigraphy is invaluable for determining the likely presence of a stress fracture in those horses that lack radiological abnormalities or in which lameness rapidly resolves. There is IRU in the distal metaphyseal region of the McIII.

Treatment

Most horses respond well to 3 months' rest, with 1 month of box rest and then box rest combined with walking exercise. Work intensity can then be progressively increased. The previous training program should be reviewed to try to identify any features that may have predisposed the horse to fracture. Extensive periosteal callus gradually remodels.

Dorsomedial Articular Fractures of the Third Metacarpal Bone

Dorsomedial articular fractures of the McIII have only been recorded in the Standardbred (STB) racehorse,¹⁷ although similar fractures have been identified in the McIII of TBs. The condition usually affects horses 2 to 4 years of age and occurs most commonly in pacers.

Clinical Signs

Lameness is acute in onset, after racing or training, and severe. Lameness persists despite rest. A bony swelling may be palpable on the proximal, dorsomedial aspect of the McIII. Direct pressure may elicit pain.

Diagnosis

Lameness is generally improved by intraarticular analgesia of the middle carpal joint. Diagnosis is based on radiological identification of the fracture, best viewed in a dorsolateral-palmaromedial oblique image. The fracture is articular, nondisplaced, and usually incomplete (Figure 37-4). Active periosteal new bone invariably exists at the distal aspect of the fracture, close to the insertion of the extensor carpi radialis tendon, even in an acute injury.

Treatment

Treatment consists of rest for a minimum of 3 months. The fractures usually heal with modeling of the periosteal reaction and progressive loss of distinction of the fracture line. Lameness resolves, and horses are able to withstand training before the fracture line completely disappears radiographically.

Stress Reactions in the Condyles of the Third Metacarpal Bone

See Chapter 36 for a discussion of stress reactions (see page 398).

Subchondral Bone Trauma

Osseous trauma of the condyles of the distal aspect of the McIII is a diagnosis made using MRI.^{18,19} There is usually acute-onset lameness with no localizing clinical signs. Pain is localized to the fetlock region using perineural analgesia. The response to perineural analgesia is often better than to intraarticular analgesia. Radiographic and ultrasonographic examinations usually reveal no detectable abnormality. Scintigraphy usually reveals IRU. There is increased signal intensity in fat-suppressed magnetic resonance images,

Fig. 37-4 • Dorsolateral-palmaromedial oblique xeroradiographic view of the proximal metacarpal region of a 3-year-old Standardbred male with a dorsomedial articular fracture of the third metacarpal bone. The wide oblique incomplete fracture line (arrows) and presence of proliferative new bone along the dorsomedial aspect of the third metacarpal bone indicate that bone activity in this region preceded the development of acute lameness. (Courtesy Mike Ross, Kennett Square, Pennsylvania, United States.)

with reduced signal intensity in T1- and T2-weighted images, in a variable distribution in the distal aspect of the the McIII. In young TB racehorses, subchondral bone trauma is thought to represent stress-adaptation mismatch and is a manifestation of stress-related bone injury (see page 398), often occurring bilaterally. However, in mature sports horses, it more often occurs unilaterally and may reflect single episode trauma. Lameness usually resolves with rest in sports horses, but young TB racehorses may be difficult to keep sound when returned to training.

Avulsion Fracture of the Third Metacarpal Bone at the Origin of the Suspensory Ligament

Avulsion fracture of the McIII at the origin of the SL occurs most commonly in young racehorses (STBs more than TBs).²⁰⁻²⁴ Some fractures described as avulsions appear to occur immediately distal to the site of attachment of the SL.

Clinical Signs

Onset of lameness usually is acute, and lameness is generally moderate to severe and unilateral. In the acute stage, the horse generally resents pressure applied over the palmar proximal aspect of the McIII. Eliciting pain may be more difficult in horses with chronic lameness. Lameness generally improves but may not resolve by box rest.

Diagnosis

In horses with acute lameness, diagnosis usually can be based on the clinical signs and ultrasonographic or radiological demonstration of a fracture. In horses with more chronic lameness, local analgesic techniques may be required. Perineural analgesia of the palmar metacarpal (subcarpal) nerves or of the deep branch of the lateral palmar nerve usually improves lameness substantially. Intraarticular analgesia of the middle carpal joint, performed by palmar or dorsal approaches, may also improve the lameness.

An avulsion fracture is best detected radiologically in dorsopalmar or slightly oblique dorsopalmar images and lateromedial, or flexed lateromedial, images. The fracture may appear as an almost straight or saucer-shaped lucent line (with the base proximal or distal) (Figure 37-5) or as a punched-out lesion.

An avulsed fragment is usually easiest to detect by ultrasonography in longitudinal images and, if displaced, appears as a discontinuity of the palmar cortex of the McIII. An incomplete fracture may be more difficult to detect. Examining the limb while the horse is bearing weight and not bearing weight can be helpful. Slight periosteal callus may be seen in horses with a more chronic fracture. A small focal tear in the dorsal aspect of the SL at the site of the fracture may be visible in transverse and longitudinal images. Nuclear scintigraphy has been used diagnostically.²⁵

Treatment

The horse should be restricted to box rest for 6 weeks, followed by box rest and controlled exercise for at least another 6 weeks. The horse should be monitored clinically, radiologically, and ultrasonographically. Lameness caused by avulsion fracture generally takes longer to resolve than in horses with primary proximal suspensory desmitis, sometimes up to 2 months. A fracture may remain detectable radiologically for between 2 and 4 months. Periosteal callus is best seen by ultrasonography and usually is undetectable until 4 to 6 weeks after injury. The total convalescent period is usually between 4 and 6 months. Most TBs ultimately make a complete recovery and return to full athletic function without recurrent injury. Occasionally the fracture fragment may sequestrate or suspensory desmitis may progress, which results in a more guarded prognosis. However, some STBs have long-term lameness that is refractory to treatment. Superior results may be achieved using osteostixis.²⁶

Osteoarthritis of the Carpometacarpal Joint

Osteoarthritis (OA) of the carpometacarpal joint is an unusual cause of forelimb lameness. It usually occurs in mature horses used for any discipline. Clusters of Arabians with severe OA have been described^{27,28} but the condition can occur in horses of any breed.²⁸

Clinical Signs

Lameness may be acute or insidious in onset and ranges from mild to severe. In my clinical experience usually no localizing clinical signs are present, although sometimes there is localized swelling associated with extensive periarticular proliferative new bone, which may be a more typical clinical presentation in Arabians and Quarter Horses.²⁸

Fig. 37-5 • A, Dorsopalmar radiographic image of the proximal aspect of the left metacarpal region of a 4-year-old Thoroughbred with acute-onset moderate left forelimb lameness. Lameness was alleviated by perineural analgesia of the lateral palmar nerve just distal to the accessory carpal bone. The curved radiolucent line (*arrows*) in the proximal aspect of the third metacarpal bone represents an avulsion fracture at the origin of the suspensory ligament. **B**, Dorsopalmar radiographic image of the proximal metacarpal region of a 3-year-old Thoroughbred with lameness of 2 weeks' duration. A punched-out radiopacity distal to a crescent-shaped lucent area (*arrows*) in the third metacarpal bone represents an avulsion fracture at the origin of the suspensory ligament.

Carpal flexion is often not restricted or resented in association with mild radiological abnormalities, but when extensive new bone formation is present carpal flexion is restricted.

Diagnosis

Lameness may be improved by palmar metacarpal (subcarpal) nerve blocks, probably because of proximal diffusion of the local anesthetic solution. Intraarticular analgesia of the middle carpal joint also improves lameness. Radiological examination usually reveals that changes are restricted to the medial or lateral side of the joint, with narrowing of the joint space between the carpus and the McII or the McIV, with subchondral increased radiopacity (see Figure 3-2; Figure 37-6) and often periosteal new bone extending along the proximal metaphyseal region of the McII or the McIV. Lucent zones may appear in the base (head) of the McII or the McIV. In Arabians and Quarter Horses the majority of radiological abnormalities were medial.²⁸

Treatment

Response to intraarticular medication of the carpometacarpal joint has been poor.^{27,28} Palliative treatment with a nonsteroidal antiinflammatory drug (NSAID) may allow horses with mild lameness to be maintained in work. Partial carpal arthrodesis may alleviate pain (see Chapter 38).^{29,30} Arthrodesis resulted in 10 of 12 horses (83%) being described as sound approximately 2 years postoperatively, but only six horses (50%) returned to ridden activity.³⁰

Osseous Cystlike Lesions in the Proximal Aspect of the Second Metacarpal Bone

Osseous cystlike lesions sometimes are identified in the proximal aspect of the McII (Figure 37-7) in association

Fig. 37-6 • Dorsopalmar radiographic image of the proximal metacarpal region of a 10-year-old gelding. Medial is to the left. Narrowing of the carpometacarpal joint on the medial aspect of the joint and radiolucent areas in the subchondral bone indicate osteoarthritis of the carpometacarpal joint.

with lameness that is localized to the proximal metacarpal or distal carpal regions. These osseous cystlike lesions occur most commonly in the presence of a first carpal bone,¹¹ which also may have radiolucent zones. These lesions often occur bilaterally, although lameness may be unilateral. These lesions are generally considered incidental abnormalities unassociated with pain, and the clinician should search for another potential cause of lameness.

Fig. 37-7 • A, Dorsomedial-palmarolateral oblique radiographic image of the proximal metacarpal region of a 7-year-old Thoroughbred. There is an osseous cystlike lesion in the second carpal bone in association with the presence of a first carpal bone. Both forelimbs were identical. **B,** Dorsomedial-palmarolateral oblique image of the proximal metacarpal region of a 6-year-old riding horse. The radiolucent areas in the palmar aspect of the second carpal bone and proximal palmar aspect of the second metacarpal bone are associated with the presence of a first carpal bone. These were incidental radiological findings not related to lameness.

Syndesmopathy between the Second and Third or Fourth and Third Metacarpal Bones

Interosseous ligaments between the McII and the McIII and between the McIV and the McIII ossify to a variable extent. Occasionally complete osseous union develops throughout the length of the bones with internal increased radiopacity of both bones. The biomechanical implications of this are currently not understood. Inflammation of the interosseous ligament with enthesioid or endosteal new bone at the ligaments' attachments was identified using MRI as the only detectable abnormality in horses with pain localized to the metacarpal region or in association with SL pathology.^{10,31}

Exostoses of the Second and Fourth Metacarpal Bones (Splints)

Exostoses on the McII or the McIV (splints) may develop because of direct trauma, resulting in subperiosteal hemorrhage and lifting of the periosteum, or instability between the McII (or the McIV) and the McIII. However, many splints do not involve the interosseous space between the McII (or the IV) and the McIII and develop without evidence of trauma. Some splints develop without associated pain and lameness, with little evidence of active inflammation, whereas others result in a localized soft tissue inflammatory reaction, pain, and lameness. The reasons for these differences are not known. Splints may occur at any level but most commonly involve the proximal half of the bone. Lesions involving the McII occur most commonly.

Lesions may develop in young, immature horses or, less commonly, in older horses. Horses with bench (offset) carpal conformation seem particularly prone to develop splints involving the McII, but often these develop without associated lameness.

Clinical Signs

Lameness may be sudden or insidious in onset and tends to deteriorate with work and be worst on hard ground. There is usually an obvious palpable swelling comprising a bony exostosis, surrounded by an edematous soft tissue reaction, with localized heat and pain on firm palpation. The swelling should be palpated carefully with the limb not bearing weight because sometimes only focal areas of the swelling appear to be painful.

It is important to assess the axial aspect of the exostosis to determine whether there may be impingement on the adjacent SL. Such horses may have had a preexisting splint that was previously inactive. The horse often has a history of more extensive soft tissue swelling developing with hard work. Lameness may be provoked by hard work but rapidly improves with rest or light work. With the limb not bearing weight it may be difficult to palpate the border of the SL adjacent to the exostosis, and pain may be elicited by firm pressure applied to this localized area of the SL.

Diagnosis

Diagnosis of a straightforward splint often can be based on clinical signs, and further diagnostic procedures may not be necessary. Radiology may be useful to document the size and activity of the exostosis (Figure 37-8). Several oblique images using soft exposures are required. Care should be taken not to confuse as fracture radiolucent lines that are caused by layers of new bone being superimposed, by incorporation of fibrous tissue, or an edge effect created by the parent bone. Radiography cannot properly document the axial extent of any exostosis.

Nerve blocks or local infiltration may be necessary to prove or disprove that an exostosis is the primary cause of pain resulting in lameness and to identify any concurrent problem(s). Diagnostic ultrasonography is essential if an

Fig. 37-8 • Dorsomedial-palmarolateral oblique image of the metacarpal region. There is smoothly outlined enlargement of the middle of the diaphysis of the second metacarpal bone, with ill-defined, irregularly outlined periosteal new bone at the distal end of the middle third of the bone. The ill-defined radiolucent lines (*arrows*) within the bone result from new bone formation and should not be confused with fractures.

impingement on the SL is suspected. Identification of echogenic tissue axial to the exostosis and contiguous with the SL may be possible (Figure 37-9). The ipsilateral border of the SL may be irregular and reduced in echogenicity. In a small proportion of horses, adhesions between the SL and the McII or the McIV can only be identified using MRI.^{8,10}

Nuclear scintigraphy is generally unnecessary, but it should be noted that even long-standing splints, which appear to be insignificant clinically, often have mild to moderate IRU compared with the parent bone. Why active bone modeling occurs is not known.

Treatment

Lameness associated with a clinically active exostosis usually resolves with rest, and the surrounding soft tissue swelling resolves. The exostosis remodels and is usually ultimately somewhat smaller. However, sometimes irregular-appearing, palisade-like new bone may persist radiologically. The time taken for the bony reaction to settle is extremely variable, ranging from 2 to 3 weeks to 2 to 3 months. This can be difficult to predict accurately and may reflect how quickly the condition was recognized and box rest instituted. Local infiltration with corticosteroids may facilitate reduction of the soft tissue reaction, but whether this alters the course of the condition is debatable. Topical application of dimethyl sulfoxide has a similar effect.

Fig. 37-9 • Transverse ultrasonographic image of the palmar metacarpal soft tissues at 14 cm distal to the accessory carpal bone. Medial is to the left. The irregular medial border of the suspensory ligament and the echogenic material (*arrowheads*) medial to it are apparent. A moderate size exostosis (splint) on the second metacarpal bone extended axially to impinge on the suspensory ligament. Granulomatous-like tissue was interposed between the splint and the suspensory ligament.

Work should not resume until firm palpation of the exostosis fails to induce pain. Premature return to work is likely to exacerbate the problem. Some degree of fitness may be maintained by swimming exercise.

Some horses seem particularly predisposed to produce large amounts of new bone. The reason for this is unknown. Large exostoses on the McII are vulnerable to direct trauma from the contralateral limb, especially if the horse moves closely in front, or dishes. Some protection may be provided by always applying protective boots when the horse is worked or turned out. In horses with severe exostoses, surgical amputation of the exostosis and more distal aspect of the metacarpal bone should be considered. Osteotomy of the exostosis and liberal removal of the surrounding periosteum from the splint bone and the McIII without removing the distal segment of the splint bone also have been cosmetically and functionally successful in some horses. Surgical technique may influence the risk of reformation of periosteal new bone.³²

In some horses chronic pain associated with a splint persists, despite appropriate conservative management. Pin-firing is suggested if pain persists longer than 6 weeks after lameness was first recognized (see Chapter 88). An additional 6 weeks of walking is required before normal work can be resumed after firing.

If there is axial impingement of the exostosis on the SL or adhesions between the splint exostosis and SL, surgical treatment is required. Amputation of the McII or the McIV proximal to the exostosis is the treatment of choice, assuming that this leaves the proximal third of the bone intact,

providing stability to the carpus. Often a granulomatous-type reaction occurs between the exostosis and the ipsilateral margin of the SL; this material should also be removed. Alternatively, segmental ostectomy can be performed. One Editor (MWR) prefers to use a different approach because instability of the proximal segment of the McII or the McIV often results in recurrence of lameness and bony proliferation at the ostectomy site. A combination of metacarpal fasciotomy, ostectomy of the exostosis on the axial aspect of the McII or the McIV, adhesiolysis, and the local deposition of antiinflammatory products such as hyaluronan is used.

Fractures of the Second and Fourth Metacarpal Bones

Fractures of the McII and McIV bones may result from direct external trauma or internal forces, frequently in association with suspensory desmitis.³³⁻³⁷ The latter is particularly common in horses that race over fences, STBs, and, less frequently, event horses.

Fractures caused by internal forces usually occur at the junction between the proximal two thirds and distal one third of the metacarpal bone. The distal ends of the McII and the McIV are connected by fibrous bands to the abaxial surface of the medial and lateral PSBs. Hyperextension of the fetlock and stretching of these fibrous bands may predispose to fracture. Suspensory desmitis may precede fracture and result in modeling and progressive deviation of the distal part of the bone away from the McIII because of pressure or adhesions, thus predisposing to fracture. Fractures at this location unassociated with suspensory desmitis are relatively uncommon, but they do occasionally occur.

Fractures Caused by Internal Trauma

Clinical Signs

Lameness is acute in onset and moderate. Diffuse edematous soft tissue swelling rapidly develops in the distal half of the metacarpal region, more extensively medially if the McII is fractured and laterally if the McIV is involved. Occasionally both the McII and the McIV bones are fractured simultaneously. One or both forelimbs may be affected. Careful palpation reveals enlargement of the body and/or branch of the SL. Palpating instability of the distal piece of the fractured bone may be possible, but extensive soft tissue swelling may prevent this.

Diagnosis

Radiographic examination should include the metacarpal bone and the ipsilateral PSB because lesions may occur at both sites concurrently. Preexisting abnormalities of the McII or the McIV suggest long-term suspensory desmitis (Figure 37-10, A). The fracture should be evaluated to determine the degree of displacement and the presence of comminution and callus. Ultrasonographic examination is performed to assess the degree of suspensory desmitis, which is the most important prognostic factor.

Treatment

Some controversy exists concerning the optimal treatment for horses with fractures of the distal third of the McII and the McIV. Some infer that most horses can be managed conservatively, whereas others advocate surgical removal of the fracture fragment. Nondisplaced or slightly displaced fractures usually heal satisfactorily within 4 to 6 weeks if the horse is confined to box rest. Only a small amount of callus develops, which subsequently remodels (see Figure 37-10, B). Small radiolucent defects may persist because of

Fig. 37-10 • A, Dorsomedial-palmarolateral oblique radiographic image of the second metacarpal bone of a 7-year-old Thoroughbred steeplechaser. There is a complete, displaced fracture at the junction between the middle and distal thirds of the bone. The axial deviation of the bone indicates previous distortion of the bone in association with desmitis of the medial branch of the suspensory ligament. Some endosteal and periosteal callus is present. **B**, Dorsomedial-palmarolateral oblique radiographic image of the second metacarpal bone of an endurance pony. There is a healing fracture of the second metacarpal bone, associated with desmitis of the medial branch of the suspensory ligament.

incorporation of fibrous tissue. If a fracture is moderately displaced, a larger amount of callus may develop, or a thick layer of fibrous tissue may be laid down, which envelops the entire distal aspect of the metacarpal bone. A large exostosis may impinge on the SL. Therefore surgical removal of these fragments is recommended. The convalescent program is dictated by the degree of suspensory desmitis. Prognosis is better in STBs than in TBs.

Fractures Caused by External Trauma

Fractures of the McII or the McIV caused by external trauma may be simple or comminuted, open or closed.

Clinical Signs

Lameness is acute in onset and is associated with soft tissue swelling around the fracture site, heat, and pain. An open wound may be present. Thorough debridement, cleaning, and lavage of open wounds are important to minimize the risks of infection.

Diagnosis

Radiographic examination is essential to determine the precise position and nature of the fracture (Figure 37-11). If the fracture is chronic or associated with an open wound, the radiographs should be appraised carefully for evidence of infectious osteitis.

Treatment

Fractures involving the proximal third of the bone may require surgical stabilization of the bone to prevent carpal instability, especially if the fracture involves McII. Insertion of small plates with screws into the McII without traversing the interosseous space is the preferred method

of management. Oblique fractures of the proximal aspect of the McII or the McIV can be repaired using 3.5-mm bone screws and stainless steel wire using the tension band principle in an intrabone technique (screws only engage the involved splint bone and not the McIII). Alternatively, screws placed between the McII and the McIII can be used, but fixation may be unstable, and chronic lameness could develop because of synostosis between the two bones or reaction from the implants themselves. When horses have simple displaced or comminuted fractures of the McII or the McIV, but with infection, all efforts should be made to resolve infection before surgical fixation is attempted. However, if the fracture is comminuted and the carpus appears to be stable, conservative management may be satisfactory. Simple or more complicated fractures in the distal two thirds of the bone can be treated either conservatively or by surgical removal, depending on the size of the pieces and their location.

DIFFERENTIAL DIAGNOSIS OF DIFFUSE FILLING IN THE METACARPAL REGION

Diffuse filling in the metacarpal region, with or without stiffness or lameness, is common. The clinician makes a diagnosis of the cause through review of the history of the horse and careful clinical examination (Box 37-1).

The clinician should assess the following points:

- Is the swelling symmetrical, or does it predominantly involve only one side of the limb?
- Does swelling extend the entire length of the metacarpal region, or only part of it?
- Has any filling occurred in the pastern region, or the carpus and proximally?
- Does the palmar aspect of the limb have a straight contour?
- Is the swelling edematous?
- What are the intensities of the digital pulse amplitudes?
- Is the limb hot or cold?
- Is the horse febrile?
- Is the horse bright and alert, or depressed?
- Is more than one limb involved?
- Are any skin lesions apparent?

BOX 37-1

Differential Diagnosis of Diffuse Filling in the Metacarpal Region

- So-called cold edema
- Cellulitis
- Edema and inflammatory reaction associated with a subsolar abscess
- Scabby skin lesions on the palmar aspect of the fetlock
- Mud fever
- Lymphangitis
- Purpura hemorrhagica
- Hemorrhage
- Filling caused by direct trauma
- Tendonous or ligamentous injury
- Thrombosis
- Fracture
- Equine viral arteritis
- Infection of a tendon
- Infection of the digital flexor tendon sheath
- Photosensitization
- Hypertrophic osteopathy

- What color is the limb?
- Is the horse sound, stiff, or lame?
- What is the severity of lameness?
- Is each anatomical structure palpable?
- Is each structure intact and of normal size and shape?
- Does palpation of a specific structure elicit pain?

Hemorrhage

Hemorrhage in the proximal metacarpal region is an occasional cause of acute-onset, severe lameness during work. Extensive soft tissue swelling rapidly develops, mimicking a severe tear of the ALDDFT. The swelling makes it difficult to palpate accurately specific structures. However, ultrasonographic examination reveals no detectable structural abnormality of the digital flexor tendons and the ALDDFT. Application of a large support bandage and treatment with NSAIDs brings rapid relief. The bandage should be maintained and changed as needed for approximately 7 to 10 days. When the bandage is removed, the limb is usually of normal contour. The limb should be reexamined by ultrasonography to confirm that no structural abnormalities exist before allowing the horse to resume normal work. The cause of this condition is unknown, and the likelihood of recurrence is small.

Thrombosis

Thrombosis of the medial palmar vein is a rare cause of lameness in the horse. Partial thrombosis may result in periodic diffuse filling of the distal limb associated with lameness. Complete occlusion may result in severe lameness and distal limb swelling soon after starting any exercise. Diagnosis is based on careful palpation of the vasculature combined with ultrasonography, including Doppler. Treatment requires vascular surgery.

Infection of Tendons

Infection of the SDFT or DDFT, without any evidence of a penetrating wound, is an unusual cause of lameness, but unless infection is recognized early and treated aggressively, it can have catastrophic consequences.³⁸

Clinical Signs

Sudden-onset, severe unilateral lameness involves a forelimb or hindlimb. Frequently this follows within 24 hours of strenuous exercise. The horse is usually reluctant to bear weight on the limb, and effective control of pain can be difficult. Considerable peritendonous edema develops rapidly, precluding accurate palpation of the digital flexor tendons. Palpation reveals localized heat and exquisite pain. The skin may become tight, and if the infection is unrecognized and untreated, pus may exude through defects in the skin within several days.

Diagnosis

Ultrasonographic evaluation reveals a central anechoic defect within the infected tendon (Figure 37-12) that progresses rapidly and may extend the length of the metacarpal or metatarsal region within a few days. In the early stages, lameness may be disproportionately severe relative to the perceived amount of tendon damage. Bacterial culture has frequently yielded a coagulase-positive *Staphylococcus*.

Fig. 37-12 • Transverse ultrasonographic image of the plantar metatarsal region. There is subcutaneous edema. The deep digital flexor tendon is enlarged and has a large anechogenic region dorsomedially (arrows) that progressed rapidly. The horse had extensive peritendinous soft tissue swelling and severe lameness associated with the infected tendon.

Treatment

Aggressive systemic antimicrobial therapy with crystalline penicillin, gentamicin, and metronidazole has usually proved inadequate, with progression of tendon destruction despite therapy. Drainage of pus and lavage combined with antimicrobial therapy has successfully controlled infection in some, but not all, horses. However, the prognosis for return to athletic function is extremely guarded.

Cellulitis, Skin Necrosis, and Necrosis of the Superficial Digital Flexor Tendon after Topical Applications

Cellulitis, skin necrosis, and subsequent necrosis of the SDFT are poorly understood conditions. The syndrome has been recognized in National Hunt racehorses.³⁹ After racing, many horses receive a topical application of a clay-like substance to the metacarpal regions, with or without overlying bandages.

Clinical Signs

Clinical signs are apparent within 24 to 72 hours and include peritendinous edema and serum ooze progressing to skin slough and exposure of the SDFT. The tendon may also be affected, without evidence of preexisting strain-type injury. Lameness varies from moderate to severe. The condition may be unilateral or bilateral. The horse may have had the same topical application previously but not necessarily so. Frequently other horses have been treated with the same batch of the proprietary claylike substance with no adverse effects. A variety of different

proprietary products have been incriminated. Curiously, to my knowledge, the condition has not been seen in event horses, although many receive similar treatments after competing.

Treatment

The condition usually progresses to a huge area of skin loss on the palmar aspect of the metacarpal region, with or without major damage to the underlying SDFT. No therapy has successfully halted this progression. Healing is by granulation tissue and fibrosis. If the horse survives, it has a massively thickened limb, and most horses have not returned to racing.

Cellulitis Associated with Superficial Digital Flexor Tendonitis

Cellulitis sometimes occurs with superficial digital flexor tendonitis. Clinical signs are usually recognized within 24 to 48 hours after competition. The horse has diffuse filling in the metacarpal region(s), and pinpoint pricks appear in the skin through which serum oozes within several days. The horse may be slightly lame or have a stiff gait. Symptomatic therapy usually resolves the majority of filling and lameness, and a primary tendon injury may go unrecognized without careful inspection. Careful ultrasonographic evaluation is mandatory because almost invariably primary tendonitis is present. Care should be taken in the presence of clinically significant subcutaneous edema because acoustic enhancement may mask a subtle tendon lesion. Such horses should be reevaluated after resolution of the edema.

Enostosis-like Lesions

Enostosis-like lesions are focal areas of new bone formation within the medullary cavity of a bone, occurring on the endosteal surface or close to a nutrient foramen. They occasionally occur in the McIII and may be single or multiple. They can occur as incidental radiological abnormalities or in association with lameness. Nuclear scintigraphy may reveal IRU at the site of these lesions, but this does not necessarily imply that associated pain exists. Clinical significance can only be ascribed by eliminating all other sources of pain.

Hypertrophic Osteopathy

Hypertrophic osteopathy, or Marie's disease, frequently involves the metacarpal region, resulting in localized or diffuse soft tissue swelling that overlies new bone formation.⁴⁰ Hypertrophic osteopathy has been associated with thoracic disease, a variety of vascular lesions, granulomatous enteritis, and some tumors in the thorax and abdomen. Identification of the primary lesion and successful treatment may result in resolution of the bony lesions and associated clinical signs.

Clinical Signs

The acute stage of hypertrophic osteopathy produces heat and edematous swelling overlying areas of new bone formation. Palpation of the affected bones produces pain. All the limbs should be inspected carefully to establish the extent of the lesions. Depending on the limbs affected, the horse may show overt lameness or generalized stiffness.

Fig. 37-13 • Dorsolateral-palmaromedial oblique radiographic image of the proximal metacarpal region using soft exposure factors to show palisading new bone (*arrows*) on the dorsal aspect of the third metacarpal bone typical of hypertrophic osteopathy. The 7-year-old breeding stallion had avian tuberculosis and was successfully treated, with the bony lesions resolving.

Although careful clinical appraisal of the entire horse may reveal clinical signs of an underlying disease process, often no clues are present. Clinical evaluation should include palpation of all lymph nodes, auscultation of the heart and lungs, and rectal examination.

Diagnosis

Radiographic examination, using soft exposures, reveals palisading periosteal new bone in the diaphyseal and metaphyseal regions of the McIII and other affected bones but usually excluding the joints (Figure 37-13). The palisading new bone, perpendicular to the cortices, is pathognomonic.

Every effort should be made to try to define the primary causal lesion. Additional diagnostic tests should include thoracic radiography and echocardiography, examination of a tracheal aspirate and peritoneal fluid, and routine hematological and clinical biochemistry testing. If weight loss is evident, an oral glucose tolerance test should be performed to assess small intestinal absorption of disaccharide sugars. A labeled white blood cell nuclear scintigraphic examination of the thorax and abdomen may be helpful. Skin biopsies may reveal evidence of vasculitis.

Treatment

If the primary cause of the condition can be identified and successfully treated, then the bony lesions will resolve spontaneously. The new bone becomes progressively more radiopaque and corticalized and gradually models to restore a more normal contour. Occasionally lesions have resolved spontaneously after treatment with phenylbutazone.

Fig. 37-14 • Dorsolateral-palmaromedial oblique image of the metacarpal region. A radiolucent zone (an involucrum) surrounds a separate radiopaque fragment within the fourth metacarpal bone (a sequestrum). Periosteal new bone appears on the diaphysis of the fourth metacarpal bone, through which is a lucent canal (a cloaca).

Osteitis or Osteomyelitis

Infectious osteitis or osteomyelitis occurs commonly in the metacarpal region because of the relative lack of soft tissue coverage of the bones and is usually a sequel to known trauma, with or without an open wound.

Clinical Signs

There is localized soft tissue swelling and mild to moderate lameness, and usually a draining tract is apparent.

Diagnosis

Ultrasonographic evaluation reveals an anechogenic region adjacent to the bone in the acute stage, as well as the accumulation of pus, before radiological changes are evident. Radiological abnormalities may include a radiolucent region within the cortex of the bone, periosteal new bone, and a sequestrum and involucrum in horses with advanced infection (Figure 37-14).

Treatment

Aggressive antimicrobial therapy sometimes successfully resolves the infection, but surgical debridement is indicated in horses with advanced sequestration.

USE OF BOOTS AND BANDAGES TO PREVENT INJURY

The use of stable bandages, protective boots and bandages for exercise, and proprietary clays and cooling agents after exercise is common among horse owners in their efforts to protect horses from injury and to help to manage

preexisting injuries. Bandages that are applied too tightly have tremendous potential to cause local damage, not only to the underlying skin on the dorsal and palmar aspects of the metacarpal region but also to the underlying tendons. The midmetacarpal region appears to be particularly vulnerable. Transient (a few hours') application of an overly tight bandage results in a "bandage bow," localized subcutaneous edema overlying the SDFT. More prolonged application of a bandage that is too tight results in hair loss and skin necrosis. Hair that regrows is white. Excessive sustained pressure causes tendon necrosis.

Persistent bandaging at appropriate pressures does not cause damage but leaves permanent rings in the hair; if these rings are visible at a prepurchase examination, they should alert the veterinarian that the horse usually stands in bandages. Properly applied stable bandages can be used to control filled legs and in horses prone to distention of the fetlock joint capsule or the DFTS.

The use of bandages or boots during exercise is somewhat controversial. A properly applied bandage should aim to permit a normal range of motion but protect against movement in an abnormal range.⁴¹⁻⁴⁸ Little evidence exists that a bandage applied circumferentially around the limb reduces loads on the digital flexor tendons and thereby reduces the risk of overstretch injury. Studies on cadaver models have shown that distal limb bandages may increase the amount of energy a limb can absorb during repeated loading.^{41,42} Strain on the proximal aspect of the SL may be decreased in a standing or walking horse.⁴³ In exercising horses, fetlock extension was reduced.⁴⁰ However, shock attenuation was unaffected.⁴¹ The effectiveness of stabilizing support bandages in people decreases rapidly with exercise, and restriction in motion may have an adverse effect

on performance in healthy athletes. Athletic taping of the fetlock of horses exercised at the trot had no effect on SDFT or SL strains; fetlock extension during stance was not affected, but there was a decrease in peak vertical force measured using a force plate.⁴⁶ In exercising horses the core temperature within the SDFT increases substantially, and although the role of temperature in tendon injury remains uncertain, bandaging has the potential to promote heating. The effects of a gamgee bandage, a neoprene boot, a three-layered bandage, and a Dalmar tendon support boot (Dalmar Ireland Ltd., Glanmire, Ireland) on fetlock extension were compared in an *in vitro* model. The Dalmar support boot reduced fetlock extension.⁴⁷ Moreover, kinematic studies of fetlock extension at walk and trot comparing four different boot designs showed a small decrease (0.5-1.5 degrees) in fetlock extension at the trot with all boots compared to without boots, suggesting that this may reduce tension in the SL and SDFT. However, studies at the canter, gallop, and jumping have not been performed. Therefore little current rationale exists for use of bandages or boots to prevent tendon strain injuries.

Boots and bandages have the potential to attenuate forces from direct trauma to the limb, for example, as the result of a horse hitting a fixed fence. However, without reinforcement, none properly protects against strike injuries from the hindlimb of the same horse or from strike injuries from adjacent horses. Such strike injuries can result in severe tendon injuries. The introduction of a more resilient bulletproof type of material into part of a boot, or applied as a palmar reinforcement under a bandage, can provide some protection against these devastating injuries, but the effect of such rigid material on normal movement of the flexor tendons is not known.

Chapter 38

The Carpus

Mike W. Ross

ANATOMY

The carpus consists of the antebrachiocarpal, middle carpal, and carpometacarpal joints. The antebrachiocarpal and middle carpal joints are considered ginglymi, but they are not typical of hinge joints; the carpometacarpal joint is arthrodial.¹ Arthrodial joints also exist between carpal bones in each respective row. Effective movement of the carpus originates from the antebrachiocarpal and middle carpal joints. The carpometacarpal joint does not open, but it is subject to shear stress. The antebrachiocarpal joint lies between the distal aspect of the radius and the proximal row of carpal bones. The distal, dorsal aspect of the radius has deep grooves in which run the tendons of the extensor carpi radialis and common digital extensor muscles. In flexion the tendons compress the dorsal aspect

of the antebrachiocarpal joint, limiting visibility when arthroscopic examination is performed. The proximal row of carpal bones includes the accessory carpal bone, which articulates with the distal aspect of the radius and the ulnar carpal bone. The accessory carpal bone forms the lateral border of the carpal canal. From lateral to medial, the ulnar carpal, the intermediate carpal, and the radial carpal bones complete the proximal row.

The middle carpal joint lies between the proximal and distal rows of carpal bones. The number of bones in the distal row varies but always includes, from medial to lateral, the second, third, and fourth carpal bones. A first carpal bone is present unilaterally or bilaterally in approximately 50% of horses¹ and should not be mistaken on radiographs for an osteochondral fragment. The first carpal bone articulates with the second metacarpal bone (McII) and the second carpal bone, and its presence is often associated with radiolucent areas in the McII. A fifth carpal bone is rare, but if present is small, articulates with the fourth carpal bone and the proximal aspect of the fourth metacarpal bone (McIV), and can be confused with an osteochondral fragment. The second, third, and fourth carpal bones articulate with the McII, the third metacarpal bone (McIII), and the McIV, respectively. The articulation of the second carpal bone and the McII is broader than is that of

the fourth carpal bone and the McIV, and hence the McII receives greater load, an important fact to consider with fractures of the McII and the McIV. The third carpal bone, the largest bone in the distal row, has two fossae separated by a distinct ridge, the intermediate (lateral) and radial (medial). The radial fossa is largest, receives greater load, and is more commonly injured. The third carpal bone is L shaped and has a large, dense palmar portion that is rarely injured.

The carpal bones are held together by intercarpal ligaments including the dense palmar carpal ligament from which the accessory ligament of the deep digital flexor tendon arises. The strong intercarpal ligaments play a major role in stability, and the palmar intercarpal ligaments have been shown to provide more resistance to extension of the carpus than does the palmar carpal ligament.² When large medial and lateral corner osteochondral fragments of the third carpal bone are removed, the intercarpal ligaments and capsular attachments must be incised. These dense attachments provide stability, which can be advantageous when slab fractures are repaired. The dorsomedial intercarpal ligament courses between the medial aspect of the second carpal bone and the dorsomedial aspect of the radial carpal bone,³ but during arthroscopic examination it appears to blend with the joint capsule. A theory was proposed that the dorsomedial intercarpal ligament became hypertrophied and impinged on the articular surface of the radial carpal bone, causing secondary modeling in young racehorses and lameness.⁴ Recent studies of normal carpi found that the dorsomedial intercarpal ligament was neither hypertrophied nor impinging on the radial carpal bone. A definite relationship exists between the development of pathological conditions on the distal aspect of the radial carpal bone and the attachment of the dorsomedial intercarpal ligament, but I have not observed hypertrophy or impingement. The majority of radial carpal bone osteochondral fragments occur within or just lateral to the attachment site of the dorsomedial intercarpal ligament. Because the dorsomedial intercarpal ligament resists dorsomedial displacement of the radial carpal bone,³ this site is prone to develop osteochondral fragments. In abnormal carpi, hypertrophy of the dorsomedial intercarpal ligament has been found to be apparent, but no correlation existed between hypertrophy and cartilage or subchondral bone damage.⁵

The medial and lateral palmar intercarpal ligaments resist displacement and dissipate axial forces by allowing abaxial translation of carpal bones.^{6,7} The long and short medial and lateral collateral ligaments originate on the radius and attach to the proximal aspects of the McII and the McIV, and the abaxial surface of the carpal bones, respectively. The collateral ligaments provided the major resistance to dorsal displacement of the proximal row of carpal bones during experimental loading, but the small but important palmar intercarpal ligaments contributed 23% resistance.² The lateral palmar intercarpal ligament mostly attaches proximally on the ulnar carpal bone and distally on the third carpal bone and may be divided,³ findings different from those previously reported—that the distal attachment was mostly on the fourth carpal bone.⁸ The medial palmar intercarpal ligament has four bundles that vary in size, and it courses between the radial carpal bone proximally and the palmaromedial surface of the

third carpal bone and palmarolateral surface of the second carpal bone distally.³ Tearing of the medial palmar intercarpal ligament and to a lesser extent the lateral palmar intercarpal ligament was observed in horses with carpal disease and was recently proposed to be associated with cartilage and subchondral bone damage (see the following discussion).^{8,9}

The carpus has a dense joint capsule dorsally that blends with the overlying fascia and retinaculum. Synovium in young horses is often thickened or folded dorsally in the middle carpal joint and can interfere with visibility during arthroscopic surgery. This fold appears to smooth as horses age or as osteoarthritis develops. The antebrachial fascia blends with the retinaculum that functions to restrain extensor tendons. Retinaculum thickens and forms the medial and palmar borders of the carpal canal. The palmar retinaculum is sometimes severed in horses with carpal tenosynovitis and tendonitis (see Chapter 75). Anatomical considerations and flexor and extensor tendon injuries are discussed elsewhere (see Chapters 69 and 77). The sheathed extensor carpi radialis and common digital extensor tendons, located dorsally and dorsolaterally, respectively, limit carpal palpation and restrict access. Cul-de-sacs of distended antebrachiocarpal and middle carpal joint capsules can be palpated medial to the extensor carpi radialis tendon or between the extensor carpi radialis and common digital extensor tendons in a standing horse. Arthrocentesis and arthroscopic examination require careful placement of needles and instruments in these portals to avoid injury to tendons and sheaths. These portals can be easily felt as distinct depressions when the carpus is flexed. The sheathed lateral digital extensor tendon, located on the lateral aspect, should be avoided during arthrocentesis of the palmarolateral pouches. The sheathed extensor carpi obliquus tendon is small and passes obliquely over the antebrachiocarpal joint from lateral to medial to attach to the McII. This tendon can readily be seen medially during arthroscopic examination of the antebrachiocarpal joint. Extensor tenosynovitis must be differentiated from middle carpal and antebrachiocarpal joint effusion and hygroma. The antebrachiocarpal and middle carpal joints each have a palmarolateral and a palmaromedial outpouching through which arthrocentesis and arthroscopic evaluation can be performed. Unless greatly distended, the palmarolateral outpouchings are larger than the corresponding palmaromedial outpouchings. The palmarolateral outpouching of the antebrachiocarpal joint is in close proximity to the carpal sheath, and inadvertent penetration of the carpal sheath can occur during arthrocentesis or arthroscopic examination even when the palmarolateral outpouching is distended.

Knowledge of the communications and boundaries of the carpal joints is important in understanding the extent of disease processes and the results of diagnostic analgesia (see Chapter 10). The antebrachiocarpal joint is considered solitary, although in a single specimen in a cadaver study the joint communicated with the middle carpal and carpometacarpal joints.¹⁰ In some horses a communication appears between the antebrachiocarpal joint and the carpal sheath. The middle carpal and carpometacarpal joints always communicate (see Figures 10-8 through 10-10). Communication between the middle carpal and carpometacarpal joints and the carpal sheath is rare. The

carpometacarpal joint has distinct distopalmar outpouchings located axial to the McII and the McIV that have secondary pouches interdigitating within the proximal aspect of the suspensory ligament (SL). These outpouchings explain inadvertent analgesia of the carpometacarpal and middle carpal joint while performing high palmar analgesia and possibly why lameness abates during middle carpal analgesia in horses with avulsion fractures of the proximopalmar aspect of the McIII or proximal suspensory desmitis.¹¹

CONFORMATION

Racehorses, especially Thoroughbreds (TBs), with offset-knee (bench-knee) and back-at-the-knee (calf-knee) conformation are predisposed to develop carpal lameness. Mild in-at-the-knee (carpus valgus) deformity is common and of little concern, but if the deformity is severe, it can predispose to carpal lameness similar to that in horses with out-at-the-knee (carpus varus) conformation (see Chapter 4).

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF CARPAL LAMENESS

Carpal lameness is a common finding in many sports horses, but it is most common in racehorses. Former racehorses used in other disciplines may have chronic osteoarthritis (OA) or recurrence of osteochondral fragmentation. Primary carpal lameness in nonracehorses occurs from trauma such as from falls, kick wounds, and hitting fences; hyperextension injury resulting in fractures of the accessory carpal bone; and occasionally primary OA. Old horses, in particular Arabian horses, appear prone to develop inexplicable chronic, often severe OA of the carpometacarpal joint. Palmar carpal injury occurs in horses that fall or during recovery from general anesthesia and can result in moderate to severe lameness and subsequent OA. Palmar carpal injury most commonly involves the antebrachiocarpal joint, and clinical signs may not develop until hours or a few days after recovery from general anesthesia. Injury may result from trauma when the affected carpus is hyperextended or flexed and usually occurs in horses during rough recoveries but can occur, inexplicably, in horses with seemingly uneventful recoveries.

Few historical facts are pathognomonic for carpal lameness unless severe swelling and lameness develop acutely or a trauma is observed. TB racehorses may lug (bear) in, lug out, or fail to change leads. A Standardbred (STB) racehorse may be on a line. Horses may be racing poorly, particularly those with bilaterally symmetrical lameness. In racehorses with right forelimb carpal lameness, signs may be worse on the turns. Although most STBs are on the ipsilateral line, rarely a horse with right forelimb carpal lameness will be on the left line, presumably because the horse is bearing away from medially located pain or has a shortened stride in the right forelimb. Nonracehorses may have poor performance, fail to change leads, and hit or refuse fences. They may be uncomfortable when studs are placed in or removed from the shoes. Ponies with antebrachiocarpal joint pain may start to stumble.

Degree of lameness varies with the type and severity of carpal injury. Horses with early or mild chronic OA have mild lameness, whereas those with acute osteochondral

fragments, slab fractures, or other more serious injuries have more severe lameness. Horses with infectious arthritis and comminuted carpal or other severe fractures may not bear weight at the walk. Dynamic angular deformity, carpus valgus or varus, may be seen in horses attempting to bear weight with comminuted fractures and loss of joint integrity. Lameness may be intermittent in horses with early and incomplete osteochondral fragments and may be apparent only after training or racing. Racehorses with bilaterally symmetrical lameness may not show overt lameness but have a wide, short gait bilaterally. Advancing and placing the affected limb wide while walking or trotting (pacing) is typical of carpal lameness (see Chapter 7). Horses with severe OA and natural carpal ankylosis or surgical arthrodesis swing (abduct) the limb because the carpus cannot flex. Advancement and placement of the limb in a lateral (abducted) position is not pathognomonic for carpal lameness, and horses with proximal palmar metacarpal pain or those with pain originating laterally in the digit may manifest similar signs. However, carpal tenosynovitis does not result in this typical carpal gait. Horses with carpal lameness have a shortened cranial phase of the stride. Lameness can be worse with the limb on the inside or outside of the circle depending on whether the location of pain is medial or lateral, but, in general, lameness in most horses with carpal lameness is worse with the limb on the *outside* of the circle.

Increased temperature (heat) over the dorsal surface of the carpus is a reliable indicator of carpal disease, but false positive and negative findings occur. If horses have been clipped for painting or blistering, or effects of topical counterirritation are still present, the area can be warm and sensitive without carpal lameness. The dorsal surface of each carpus should be evaluated and compared, but differences are difficult to detect if lameness is bilateral. Effusion is usually a reliable indicator for carpal synovitis, but it is not pathognomonic for carpal lameness. Horses with subchondral bone injury without overlying cartilage damage or incomplete osteochondral fragments often have carpal lameness without effusion. Effusion is suppressed in horses that have recently had corticosteroid injections. Effusion occurs commonly in young horses with early carpalitis and in horses with advanced cartilage damage, osteochondral fragments, and infectious arthritis. Swelling associated with distention of the antebrachiocarpal or middle carpal joints is orientated horizontally on the dorsal aspect of the carpus, whereas effusion in a tendon sheath results in a longitudinally orientated swelling, compressed at intervals by horizontally orientated retinacular bands. With the horse's limb in a weight-bearing position, the clinician's fingers are used to ballot fluid within a distended carpal joint capsule. Capsular swellings are located between extensor tendons and medial to the tendon of the extensor carpi radialis. Older horses with chronic carpal changes often have mild or moderate effusion but can perform satisfactorily. In some horses there may be focal dorsal herniation of the antebrachiocarpal or middle carpal joint capsules.

Horses with acute carpal lameness, especially those with synovitis, often show a marked response to static flexion of the carpus. Horses with carpal tenosynovitis or other palmar carpal lameness also respond. Horses with pain from the proximal aspect of the limb, such as myositis in the proximal aspect of the antebrachium or elbow region

pain, respond to carpal flexion (false-positive response). Static and dynamic flexion can be negative in horses with carpal lameness, especially in those with subchondral bone pain. Degree of flexion is usually decreased in horses with chronic OA because of joint capsule fibrosis. Careful palpation of all bony and soft tissue structures of the carpal region should be performed with the limb in standing and flexed positions, and responses should be compared with the contralateral limb. Swellings are best felt with the horse's limb in a standing position. Swellings of nearby sheaths should be differentiated from authentic carpal effusion by location and ballottement. Horses with chronic OA often have firm, fibrous thickening at joint capsule attachments. Dorsomedial bony swelling of the radial and third carpal bones is observed and palpated in horses with chronic severe OA. The proximal aspect of the McII and the McIV should be palpated for bony and soft tissue swelling associated with fracture or exostoses. The proximal palmar metacarpal region should be palpated with the horse in the standing and flexed positions to differentiate pain in this region from carpal pain. The superficial digital flexor tendon should be carefully palpated to detect enlargement and pain, because horses with proximal superficial digital flexor tendonitis often manifest a positive response to carpal flexion. However, swelling of the superficial digital flexor tendon is easily overlooked because of compression by the extensive palmar retinaculum.

In my experience, the carpal flexion test is the most specific of any flexion test used, and if the test result is positive, carpal *region* pain is highly probable. A positive test result does not always incriminate the carpal joints, and the surrounding soft tissue structures must be kept in mind. A negative test result does not rule out carpal pain. Horses with subchondral bone pain, usually young racehorses with sclerosis of the third carpal bone, often have a negative or equivocal response to flexion. Horses with palmar metacarpal or elbow pain can respond positively.

Diagnostic Analgesia

In many horses, clinical signs and characteristic gait may allow a tentative diagnosis of carpal lameness, but in most horses diagnostic analgesia should be performed. Analgesia of the middle carpal and antebrachiocarpal joints should be performed independently and sequentially. Dorsal intraarticular techniques are most common, but in horses with scurf from previous counterirritant application or dorsal wounds, the palmarolateral pouches are used. Careful selective perineural and intraarticular analgesic techniques should be performed to differentiate between proximal palmar metacarpal pain and authentic carpal pain (see Chapter 10). Intraarticular analgesic techniques are highly specific, but false-negative results may occur.¹² False-positive results may also result because of abolition of carpal sheath pain or proximal palmar metacarpal region pain. Subchondral bone pain may not always be eliminated by intrasynovial deposition of local anesthetic solution, because nerve fibers may be located in bone or travel to the site by another extrasynovial route. The median and ulnar nerve block, although lacking specificity, is useful in horses with suspected carpal region pain that is not abolished by intraarticular techniques.

Laboratory analysis of synovial fluid is reserved for horses in which acute inflammation or infectious arthritis

is suspected, but color and viscosity should be evaluated, and abnormalities may help to convince an owner or trainer of a carpal problem. In a normal flexed carpus, fluid does not readily drain from a small-gauge needle, and compression of the joint capsule at a distant site is usually necessary. Horses with effusion have thin synovial fluid that drips spontaneously without compression of the nearby capsule. Horses with true serosanguineous fluid (as opposed to contamination by penetration of capsular or synovial vessels) likely have cartilage damage with exposed subchondral bone or an osteochondral fragment. Hemarthrosis can be caused by trauma or bleeding from a torn intercarpal ligament.

Imaging

Radiography

A minimum of six well-exposed and positioned radiographic images are necessary for comprehensive examination of the carpus, including the dorsopalmar (DPa), lateromedial (LM), dorsal 45° lateral-palmaromedial oblique (DL-PaMO), dorsal 45° medial-palmarolateral oblique (DM-PaLO), and flexed LM images and the dorsoproximal-dorsodistal (tangential, skyline) image of the distal row of carpal bones. The skyline image is most important for assessing subtle radiological changes of the third carpal bone, but well-positioned images are often difficult to obtain. Evaluation of the radial fossa requires flexion of the limb in the sagittal plane with the metacarpal region beneath the antebrachium (Figure 38-1). Lateral positioning of the distal part of the limb results in overlap of the radial fossa of the third carpal bone and the radial carpal bone. The skyline image underestimates the amount of increased radiopacity of the third carpal bone and magnifies normal anatomy and lesions approximately twofold.¹³ The skyline image is not a true proximal-to-distal view of the second, third, and fourth carpal bones, and therefore lesions located palmar to the dorsal edge of the radial carpal bone cannot be seen. The skyline image cannot be used to evaluate fracture lines located more than 8 to 10 mm from the dorsal edge of the third carpal bone or to differentiate large osteochondral fragments from frontal slab fractures of the third carpal bone. Additional images, such as the tangential image of the proximal row of carpal bones (used to identify osteochondral fragments and unusually located frontal or sagittal slab fractures), flexed oblique images (e.g., DL-PaMO view with the limb held in flexion for evaluation of the articular surfaces of the third and radial carpal bones), and weight-bearing, oblique images of different obliquity (e.g., off DPa views, used to identify sagittal slab fractures of the third carpal bone) are sometimes useful. Considerable confusion arises in description of oblique images, with the use of terms *lateral* and *medial oblique* instead of naming the images according to the direction of the x-ray beam. To most clinicians, the lateral oblique is equivalent to a DL-PaMO image, but to others it is just the opposite. Follow-up radiographic examination is recommended in 10 to 14 days if fracture is suspected but initial radiological findings are negative or equivocal.

Normal radiological anatomy of the carpus is difficult because carpal bones overlap considerably, bones shift during flexion, and normal radiolucent defects and aberrant carpal bones can be difficult to interpret. In the skyline

Fig. 38-1 • **A**, A well-positioned dorsoproximal-dorsodistal (skyline) radiographic image of the distal row of carpal bones requires that the third metacarpal bone be aligned directly under the radius. This makes the radial fossa visible. **B**, Resulting digital radiographic image shows radial (R) and intermediate (I) fossae of the third carpal bone (C3) (medial is to the right and palmar is uppermost). There is dense increased radiopacity of the radial fossa. Sometimes overlap of the normal articulation between the third and fourth (C4) carpal bones appears as a linear radiolucent defect (*white arrow*) in the lateral aspect of C3, a finding confused with sagittal fracture of that bone. Often when digital radiographic techniques are used, fracture lines not visible on conventional radiographs can be seen, such as in this 3-year-old Thoroughbred colt with a small osteochondral fragment of the radial carpal bone (*black arrow*). The fracture fragment is superimposed on C3 but can readily be seen. **C**, Intraoperative arthroscopic photograph showing the chip fracture (*arrow*) and surrounding cartilage damage on the radial carpal bone (RC) in this horse. **D**, Intraoperative arthroscopic photograph showing thin articular cartilage and partial-thickness cartilaginous defects on C3 (*arrows*) that accompany sclerotic subchondral bone.

image of the distal row, the normal articulation between the third and fourth carpal bones can be superimposed on the lateral aspect of the third carpal bone and confused with a sagittal fracture (see [Figure 38-1, B](#)). On a DM-PaLO image the normal articulation between the second and third carpal bones should not be confused with a sagittal

slab fracture, but this image is essential to diagnose sagittal fracture of the third carpal bone correctly, which runs parallel to this articulation. Radiolucent defects or osseous cystlike lesions are often seen in the ulnar carpal bone and are considered incidental findings, but when they appear in other bones, they can cause lameness regardless of

Fig. 38-2 • Dorsal 45° lateral-palmaromedial oblique radiographic image of a left carpus in a 2-year-old Standardbred colt. A fifth carpal bone is present (arrow). Note the lucent area in the proximal aspect of the fourth metacarpal bone. Fifth and first carpal bones should not be confused with osteochondral fragments.

whether communication with a joint exists. In LM and oblique images, the first and fifth carpal bones can be confused with osteochondral fragments. Radiolucent defects in the McII and the McIV often occur in the presence of the first (see Figure 37-7) and fifth (Figure 38-2) carpal bones but are normal. In a flexed LM image the radial carpal bone moves distally relative to the intermediate carpal bone. This normal finding is quite useful in determining the exact positioning of osteochondral fragments or other lesions on the proximal or distal surfaces of the radial and intermediate carpal bones. The flexed LM image is also highly useful for evaluation of the distal dorsal articular surface and subchondral bone of the radial carpal bone. Xeroradiography has largely been discontinued, but computed radiography and digital radiography are available at most institutions and many private practices and yield images superior to those obtained by conventional radiography, but positioning and exposure must still be optimized. Subtle radiological changes can be readily seen in most digital radiographic images, as can fragments, radiolucent defects, and other changes not previously visible on conventional images (see Figure 38-1). Care must be taken not to confuse normal articulations for fractures.

Computed tomography (CT) is available at some institutions and private referral hospitals and can be of value to determine fracture configuration and the presence of comminution, such as that demonstrated in a recent report of an Arabian filly with carpal instability, in which comminution that was not seen when digital radiography was used was confirmed with CT.¹⁴ Magnetic resonance imaging (MRI) has potential to be useful in the diagnosis of carpal region soft tissue and bony injuries but may have limited value because it is currently difficult to position a horse within some magnets to comprehensively evaluate the

entire carpal region. Through use of ex vivo MRI, minor cartilage lesions and sclerotic subchondral bone have readily been seen in intact cadaveric specimens.¹⁵ Magnetic resonance (MR) contrast arthrography has been compared with arthroscopy and gross necropsy examination to evaluate and define the lateral palmar outpouching of the middle carpal joint.¹⁶ All structures of the palmarolateral outpouching including portions of the lateral collateral and lateral palmar intercarpal ligaments were visible in MR images, and information obtained compared favorably with arthroscopic examination performed after synovectomy using a motorized intraarticular blade.¹⁶ Ultrasonographic examination of the carpus can be useful to determine the extent of soft tissue damage, to determine if wounds or fistulous tracts communicate with carpal joints, and to diagnose extensor and digital flexor tendon injury, carpal tenosynovitis, and desmitis. Using ultrasonographic examination, the body and division into medial and lateral branches of the medial palmar intercarpal ligament could be seen from a dorsal approach, and the technique may be useful to image horses suspected of having injury of the ligament.¹⁷

Scintigraphy

Scintigraphy is especially useful to diagnose early stress-related subchondral bone injury and differentiate carpal lesions from those of the proximal metacarpal region (see Figure 19-19). A common finding in young racehorses is carpal lameness localized by clinical signs and diagnostic analgesia with negative or equivocal radiological abnormalities. Focal areas of increased radiopharmaceutical uptake (IRU) are often found unilaterally or bilaterally, most commonly in the third carpal bone (see Figure 19-16). Scintigraphy can be used to verify or refute the importance of sclerosis in the third carpal bone. Scintigraphy is useful in diagnosing unusual fractures of the palmar aspect of the third carpal bone, corner fractures or table surface collapse of the third carpal bone or other carpal bones, and lesions that are not apparent or are located in obscure areas not depicted radiologically. Focal areas of IRU occur with many carpal injuries, and although sensitivity is high, the specificity of scintigraphic images is low and differentiation of specific types of injuries is difficult. Scintigraphy is most useful in localizing the site of injury, based on which additional radiographic images are obtained, or rest is recommended, followed by repeated radiographic examination.

In general, scintigraphic examination is used when lameness is localized but a specific diagnosis cannot be made. In racehorses referred for evaluation of poor performance and obscure high-speed lameness, comprehensive scintigraphic examination of all limbs often reveals focal areas of IRU in the carpus, even when evidence of overt lameness is lacking. Areas of IRU are in locations typical for horses to develop osteochondral fragments and signs of OA. Whether these areas of IRU represent sources of pain causing high-speed or subtle lameness is unknown, but often radiological evidence of bone modeling (increased radiopacity, marginal osteophytes) or incomplete osteochondral fragments exists. Treadmill exercise of previously untrained horses has resulted in a significant IRU,¹⁸ a finding indicating scintigraphy can be useful to monitor skeletal response to exercise in normal horses. Mild IRU is seen as an adaptive response to bone modeling associated

with exercise. In contrast, earlier work in normal horses showed exercise significantly increased subchondral bone density and uptake of radiopharmaceutical in the McIII condyles, but neither parameter increased significantly in carpal bones.¹⁹ More recently, in horses undergoing exercise after experimentally induced OA of the middle carpal joint, scintigraphic changes (IRU) were significantly correlated with lameness and increased beyond the normal adaptive response seen in association with exercise.²⁰

Diagnostic Arthroscopy

Specific diagnosis is usually made before surgery, and in most racehorses arthroscopy is interventional rather than diagnostic. When results of thorough clinical, radiographic, and scintigraphic examinations are combined, a specific site of injury is usually identified. In racehorses, lameness of the carpus without scintigraphic or radiological abnormalities is unusual. Lack of subchondral bone involvement leads the veterinarian to suspect soft tissue diseases such as synovitis and intercarpal ligament tearing. In these horses, careful examination of the proximal palmar metacarpal region and carpal canal should be performed to avoid inadvertent misdiagnosis. Arthroscopic examination then is used to eliminate primary cartilage damage or intercarpal ligament tearing, but often arthroscopic findings can be unrewarding. Without overt cartilage damage the prognosis is favorable, so information gained by arthroscopic examination is useful, even if a primary diagnosis cannot be made. In sports horses the frequency of carpal joint injury is less than in racehorses but arthroscopy has proved invaluable for identification of focal full-thickness cartilage defects in the middle carpal joint and palmar intercarpal ligament injury. Recently, arthroscopic approaches to the palmarolateral and palmaromedial outpouchings of the antebrachiocarpal and middle carpal joints were refined, and it was proposed that approaches to these pouches would be useful to remove fracture fragments and to evaluate palmar intercarpal ligaments.²¹ I have used approaches to these joints to remove fragments from both the antebrachiocarpal and middle carpal joints, the results of which are discussed subsequently.

In horses with scintigraphic evidence of IRU and those with OA but without radiological confirmation of osteochondral fragmentation, arthroscopic examination usually reveals cartilage damage, the extent of which can be graded. Prognosis is inversely related to degree of cartilage damage (see Figures 23-7 and 38-1). Occult osteochondral fragments, most commonly involving the third and radial carpal bones, and intercarpal ligament tearing are found frequently in these horses (see Figure 23-4).

SPECIFIC CONDITIONS OF THE CARPUS

Osteoarthritis

OA is the most common carpal problem, but clear differentiation of OA from osteochondral fragmentation is difficult, because both problems are intertwined. Horses with osteochondral fragments often develop OA, and horses with early OA, and some with chronic OA, develop osteochondral fragments. Pathogenesis of OA and osteochondral fragmentation appears similar if not identical in some horses, but OA of the equine carpus has two forms. The most common form is seen in racehorses or ex-racehorses

that initially develop stress-related subchondral bone injury of the middle carpal and antebrachiocarpal joints that leads to, or accompanies, overlying cartilage damage and osteochondral fragmentation (see Figure 38-1). A second form of OA develops in nonracehorses and is less common. Horses are usually middle aged or older, but occasionally it occurs in younger horses. Typical clinical and radiological evidence of OA exists, but osteochondral fragments are unusual (see Chapters 61 and 84).

OA in racehorses develops from a continuum of stress-related subchondral bone injury and cartilage damage, resulting from impact loading of the carpal bones during training and racing. This process has been studied most thoroughly in the third carpal bone but also occurs in other bones of the middle carpal and antebrachiocarpal joints. Sclerosis of the dorsal aspect of the third carpal bone is an adaptive response in racehorses.^{23,24} With continued loading the third carpal bone becomes densely sclerotic, and in this stage the response becomes maladaptive or nonadaptive and pathological. Subchondral changes precede those in overlying cartilage, a finding seen experimentally²⁵ and clinically during arthroscopic examination in horses with primary stress-related subchondral bone injury (see Figure 38-1). Sclerotic subchondral bone may induce overlying cartilage damage from abnormal shear forces existing between normal and sclerotic areas.²⁶ In most horses sclerosis leads to areas of resorption and necrosis, which then lead to osteochondral fragmentation and eventually to more advanced OA.^{6,23,27,28} A possible explanation for bone failure is the lack of support of overlying sclerotic subchondral bone by structurally weakened underlying trabecular bone.²⁹ When carpal bone morphology and metabolism were studied in TB racehorses and unraced controls, racehorses were found to have a net increase in bone formation, leading to stiffer, sclerotic subchondral bone; but in addition, they had increased bone collagen synthesis and remodeling in adjacent trabecular bone that may have been structurally weakened.²⁹ Because many of the changes in early OA in racehorses are mechanically induced, factors such as faulty conformation, intense exercise programs, and differences between racing breeds alter the rate of development and severity of OA. The pathological process continues, and some horses develop OA without osteochondral fragments, whereas others develop osteochondral fragments initially and then OA secondarily.

In many racehorses extensive OA and osteochondral fragmentation lead to retirement, but some are able to compete in other sporting events. Progressive OA can then develop later in life. In middle-aged to old nonracehorses, primary OA develops without stress-related subchondral bone injury, high-impact loading, or development of osteochondral fragmentation. This condition can be seen in Western performance horses, other sports horses, or even in horses and ponies used for pleasure riding. Often severe radiological evidence of OA is seen on initial examination when lameness is subtle (Figure 38-3). In fact, it has been proposed that the threshold of pain in riding horses with severe OA of the antebrachiocarpal joint may be higher than in those with similar conditions of the middle carpal joint, because observation of lameness by owners of these horses was a late event.³⁰ Faulty conformation such as carpus valgus, back at the knee, or bench knee is seen

Fig. 38-3 • Lateromedial digital radiographic image of the right carpus of an aged Quarter Horse gelding with advanced osteoarthritis of the antebrachiocarpal joint. Extensive marginal osteophyte formation in both the dorsal (*large arrow*) and palmar (*small arrows*) aspects of the joint can be seen. It is often difficult to determine if osteophytes represent osteoarthritic change or are actually small osteochondral fragments, but the close interrelationship of the most common causes of carpal lameness can be seen.

in some horses, but in others neither mechanical nor training-related factors are present. OA in these horses can involve the antebrachiocarpal and middle carpal joints together or separately, but when disease involves the carpometacarpal joint, chronic and severe lameness develops (see Figure 3-2).

Clinical Signs and Diagnosis

Clinical signs of OA vary depending on age and use of horse, but they are similar to those of other carpal diseases. Classic signs of OA, such as obvious lameness, typical carpal gait, effusion, and a painful response to static and dynamic flexion, may be present, particularly in horses with advanced OA and in old horses with severe changes, but clinical signs can be subtle in young racehorses. In racehorses with early OA, historical information such as lugging in or out, being on a line, or poor performance may be present. Effusion varies, and absence of this clinical sign does not preclude the carpus as the source of pain. Carpal lameness was common in young STB racehorses, occurring in 28% of horses in training, and was attributed to subchondral bone pain and early sclerosis, because in most horses there was little to no effusion of the middle carpal joint.³¹ Overall, carpal lameness was the most common cause for more than 1 month of rest (wastage) and was thought to be accentuated by speed training and poor forelimb conformation.³¹ Racehorses in early training are prone to develop effusion primarily of the middle carpal joint, but the antebrachiocarpal joint can also be involved. Effusion may be most evident after work, but lameness usually is not present. Effusion usually results from strain of soft tissues, such as intercarpal ligaments or the joint

capsule, but in horses with more advanced OA, effusion represents inflammation caused by continued cartilage damage. Clinical signs resolve after a brief period of rest or reduction in training. Most commonly, racehorses with early OA manifest clinical signs later in training as a 2-year-old or when racing begins.

Diagnosis should be confirmed using diagnostic analgesia of the involved joint(s). In horses with severe OA, complete resolution of lameness may not occur until median and ulnar blocks are performed. After pain in the primary limb has been abolished, lameness may be seen in the contralateral limb, indicating bilateral carpal lameness.

Radiological evidence of OA in young horses is often lacking, but increased radiopacity of the third carpal bone may be seen in a skyline image (see discussion of small osteochondral fragmentation). Early radiological changes include mild enthesophyte formation, most common on the radial carpal bone, and subtle marginal osteophytes on the carpal bones and distal radius. In horses with advanced OA, marginal osteophytes and enthesophytes become numerous and large, sometimes causing obvious visible bony swelling (see Figure 38-3). Loss of joint space occurs late in OA, but it is not an obvious radiological sign. Osteochondral fragments may be present, can be numerous, and may have occurred earlier during a racing career or can develop when marginal osteophytes break. Radiological evaluation of the contralateral carpus should be performed.

Scintigraphic examination is an excellent tool for diagnosis of early OA in racehorses, but IRU must be differentiated from mild normal adaptive increased uptake of radiopharmaceutical.^{18-20,31} Initially, focal areas of IRU are located on one side of a joint, such as in the third carpal bone, but later, subchondral IRU can be seen diffusely in one or more joints. Arthroscopic examination may be useful to establish prognosis and to evaluate possible soft tissue injury, such as intercarpal ligament tearing, and may be useful therapeutically.

Management

Management of OA is discussed in Chapter 84. Because pathogenesis involves stress-related subchondral bone injury, an important part of management of OA in racehorses involves stress relief by enforced rest or a reduction in training or racing intensity. Racehorses (STBs) without obvious radiological changes are given 2 to 3 weeks of hand walking or walking in the jog cart, nonsteroidal antiinflammatory drugs (NSAIDs), and local therapy such as cold water hosing or icing. Topical counterirritation is still a popular management technique administered to young racehorses early in training. Intraarticular administration of hyaluronan, with or without a short-acting corticosteroid, may help in horses with synovitis, but it is of limited value if the primary source of pain is subchondral bone with intact overlying cartilage. In racehorses with advanced sclerosis of the third carpal bone and early enthesophyte and marginal osteophyte formation, extended rest of 3 to 4 months is recommended. However, economic factors may dictate that these horses remain in training; thus work intensity often is decreased and horses receive a single or a series of intraarticular injections with hyaluronan or polysulfated glycosaminoglycans (PSGAGs). Horses with radiologically apparent osteochondral fragments are surgical candidates, but postoperative progression of OA and recurrence of

fragmentation are common. As OA progresses in horses with or without osteochondral fragments, numerous intra-articular injections, often including methylprednisolone acetate, may be necessary to reduce inflammation, but if training and racing continue, OA progresses in an accelerated fashion. Bisphosphonate administration in combination with a modification in exercise or rest may have a beneficial effect, but more clinical study is necessary.

A syndrome has been recognized in ponies with OA of the antebrachiocarpal joint. These ponies are presented for examination because of repetitive stumbling when ridden. There is generally resentment of carpal flexion and restricted flexion, although no obvious lameness. Although the response to intraarticular analgesia may be disappointing, the response to intraarticular medication is often good. Although historically sclerosis of the third carpal bone has been considered a disease of the racehorse, it has also been recognized as a cause of intermittent lameness in both endurance horses and event horses. Focal areas of full thickness cartilage loss in the medial aspect of the middle carpal joint have been identified arthroscopically in a small number of show jumpers that had no localizing clinical signs, lameness that was improved by intraarticular analgesia, and no detectable radiological abnormality. Some sports horses with carpal OA show lameness only when ridden and not under other circumstances. In ex-racehorses or nonracehorse sports horses with primary OA, radiological changes may be advanced when lameness is first recognized, because OA is chronic and well tolerated. Conservative management is recommended and includes rest, NSAID therapy, and intraarticular injections. Horses with radiological evidence of large intact or broken osteophytes or old osteochondral fragments may be considered candidates for arthroscopic surgery, but although arthroscopic examination may be important to establish prognosis, surgical removal of osteophytes and old osteochondral fragments does not often result in long-term clinical improvement and may accelerate progression of OA (see Figure 38-3). Involvement of the carpometacarpal joint warrants a guarded prognosis.

Prognosis depends on the number of joints and limbs affected, rate of progression of clinical signs, severity of cartilage damage, presence of osteochondral fragments, and level of competition. Most racehorses with early OA and even those with radiological evidence of osteophytes and enthesophytes can race at some level, if the horses raced before diagnosis. Horses with advanced changes before racing begins, particularly those with faulty conformation, are unlikely to race but can be sound enough to perform other sporting activities. Valuable horses with severe OA, such as broodmares or breeding stallions, may be candidates for partial (intercarpal) or pancarpal arthrodesis.

Trauma to the craniodistal aspect of the radius and dorsal aspect of the carpus may result in the rapid development of periarticular new bone on the distocranial aspect of the radius and the dorsal aspect of the intermediate carpal bone. There is often associated diffuse soft tissue swelling. Lameness may be absent or mild, but there is marked resentment of carpal flexion, and flexion may induce moderate-to-severe lameness. I speculate that this occurs because of pressure mediated by the extensor tendons on this new bone.

Osteoarthritis of the Carpometacarpal Joint

Primary osteoarthritis of the carpometacarpal joint is unusual to rare but occurs primarily in old horses, especially Arabians,³² and is insidious and progressive (see Figure 3-2 and Chapter 37).

Osteochondral Fragmentation

Small Fragments

Osteochondral fragmentation is a disease primarily of racehorses or ex-racehorses, and pathogenesis is identical to that described for OA. I prefer to use the terms *carpal osteochondral fragments* (osteochondral fragments) and *osteochondral fragmentation* instead of *carpal chip fractures* to emphasize the importance of pathogenesis. The term *chip fracture* implies a single event traumatic injury. Although trauma plays a role, osteochondral fragments are not single-event injuries but are the end result of stress-related subchondral bone injury caused by repetitive loading, initially an adaptive response but later becoming nonadaptive remodeling and pathological.^{23,25,27,28} Sites located dorsally are prone to develop osteochondral fragments. Osteochondral fragments differ in size and number of joints affected. Small osteochondral fragments are those that involve one joint surface, such as either the middle carpal or the antebrachiocarpal joints. Large osteochondral fragments that involve two joint surfaces are called slab fractures. Often, advanced changes occur in subchondral bone, such as sclerosis of the third carpal bone or other evidence of modeling or remodeling that preceded development of lameness and osteochondral fragments, findings that support the concept that osteochondral fragments are not single-event injuries. The antebrachiocarpal joint is more susceptible to injury from supraphysiological loads or acute overload injury,⁶ particularly in fatigued horses, but fractures still occur associated with pathological conditions of the bone. Palmar carpal osteochondral fragments, such as those involving the accessory carpal bone or other bones of the antebrachiocarpal joint, occur as single event injuries such as falls, carpal hyperextension, or recovery from general anesthesia. Palmar carpal fragments in the middle carpal joint are often seen in combination with other dorsally located small or large osteochondral fragments (see later).²²

In my experience, faulty conformation such as back at the knee predisposes TB and STB racehorses to develop osteochondral fragments, and trotters are more at risk than pacers. However, in a study attempting to evaluate the role of back-at-the-knee conformation in the development of osteochondral fragments in 21 horses, no differences in carpal angle were found compared with 10 horses without osteochondral fragments.³³ No association between back-at-the-knee conformation and the development of carpal lameness was found in recent studies in TBs and Quarter Horses (QHs), but elite horses were studied, and those with faulty conformation may have been excluded.^{34,35} Somewhat surprising, mild carpus valgus conformation was proposed to be protective against carpal lameness, and an association between increased humeral length and carpal lameness was found (see Chapter 4).³⁰

Carpal osteochondral fragments occur in defined locations in all racehorses, but distribution varies depending on the type of racehorse. In the STB, osteochondral fragments occur almost exclusively in the medial aspect of the

middle carpal joint and rarely in the antebrachiocarpal joint.³⁶ Although rare, osteochondral fragments in the STB antebrachiocarpal joint are most common in trotters and usually involve the distal aspect of the radius. In the middle carpal joint we found a nearly equal distribution of osteochondral fragments between the radial and third carpal bones, but in another study those of the third carpal bone outnumbered osteochondral fragments of the radial carpal bone by 2:1.^{36,37} The preponderance of osteochondral fragments in the medial aspect of the middle carpal joint in the STB is interesting, because training involves clockwise and counterclockwise exercise, whereas racing is counterclockwise. The assumption is that counterclockwise direction of training and racing places asymmetrical and uneven load distribution on each forelimb and may predispose the lateral aspect of the left forelimb and medial aspect of the right forelimb to compression injury. In two STB studies a nearly equal distribution of osteochondral fragments was noted between left and right middle carpal joints,^{36,37} but in another study osteochondral fragments of the third carpal bone occurred more commonly in the right carpus.²⁸ Trotters were more likely to have right osteochondral fragments and had significantly more osteochondral fragments of the third carpal bone than the radial carpal bone compared with pacers.²⁸

In TBs in North America, third carpal bone fractures occur more commonly in the right carpus, but considering all small osteochondral fragments, the distribution between left and right is similar.^{27,28,37} Palmar osteochondral fragments were more common in the right carpus, reflecting the preponderance of TB racehorses in that study and the fact that most fragments originated from co-existent dorsally located small or large osteochondral fragments.²² In TB and QH racehorses, osteochondral fragments are commonly seen in the middle carpal and antebrachiocarpal joints.³⁷⁻³⁹ These breeds in North America have a predilection for development of osteochondral fragments in the lateral aspect of the left antebrachiocarpal joint and the medial aspect of the right middle carpal joint, a distribution supporting the concept that osteochondral fragments develop on the compression side during counterclockwise training and racing. Overall, in TB and QH racehorses the most common sites for osteochondral fragments are the proximal aspect of the third and distal aspect of the radial carpal bones,^{22,37,39} followed by the proximal aspect of the intermediate carpal bone and the distal lateral aspect of the radius. Osteochondral fragments often develop on apposing surfaces, supporting the concept that certain sites are biomechanically at risk. This may be evident radiologically, but in some horses apposing fragmentation is identified only at arthroscopic surgery, and both limbs should be examined radiographically routinely, even if clinical signs are absent. Osteochondral fragments can be found at numerous sites in one or both carpi. Differences between racing breeds in distribution of osteochondral fragments may be explained by gait and sites predisposed to stress-related subchondral bone injury. Almost all STB osteochondral fragments occur medially, equally in both middle carpal joints. Most forelimb scintigraphic changes in STBs occur medially, indicating that the medial aspect in both forelimbs is at risk for stress-related subchondral bone injury. Classic training programs include many miles each day of jogging (trotting or pacing) clockwise (the wrong

way of the track), and training one to two times each week counterclockwise (the right way). Although all speed is performed in one direction, STBs jog many more miles in the other direction, and the number of loading cycles may be more important than speed. Direction of training and racing is not the only factor influencing fracture location because QHs and TBs have a similar distribution yet race differently. The two-beat trot and pace and a more caudal center of balance with a cart and driver result in reduced carpal loads in STBs at speed compared with galloping racing breeds. The low occurrence of osteochondral fragments in the antebrachiocarpal joint of STBs may reflect absence of supraphysiological loads. Racing speeds in the STB are lower than in the TB and substantially lower than in the QH. Fatigue rather than speed of racing may be a factor.

Clinical Signs

Lameness in horses with small osteochondral fragments varies from subtle to severe. In most horses, prominent-to-severe lameness is seen immediately after the fracture occurs, but subtle prodromal clinical signs are often present. Historically, horses may have been treated for suspected carpal lameness, may be on a line (STB), may lug in or out, or may fail to take a lead or change leads. Degree of lameness depends on location and number of osteochondral fragments and whether osteochondral fragments are present bilaterally. Horses with third carpal bone osteochondral fragments, and in particular incomplete fractures, show more pronounced lameness than those with osteochondral fragments elsewhere. Lameness is increased when the affected limb is on the outside of the circle in horses with osteochondral fragments in the middle carpal joint, but this response varies in those with osteochondral fragments in the antebrachiocarpal joint. TB and QH racehorses with osteochondral fragments of the distal, lateral aspect of the radius or proximal aspect of the intermediate carpal bone may show only mild signs of lameness. I have always thought the antebrachiocarpal joint was more "forgiving" than the middle carpal joint, with horses able to endure more substantial injury or larger osteochondral fragments, without showing overt signs of lameness, an observation shared by others.³⁰ Horses with bilateral osteochondral fragments may show minimal overt lameness. Horses with lameness inappropriately severe for the location, number, or size of fragment(s) present may have substantial cartilage damage.

There is generally effusion and heat over the carpus, but in horses with incomplete fractures, clinical signs can be subtle. Palpation may reveal a focal painful response over the site of fragmentation, and occasionally fragments can be palpated directly. Degree of flexion varies, but usually the response to a carpal flexion test is positive. Signs of OA including joint capsule fibrosis and enthesophyte production are common, particularly in horses with chronic lameness. Arthrocentesis usually reveals serosanguineous fluid, particularly if lameness is acute. Intraarticular analgesia usually, but not always, abolishes signs of pain.

Radiographic examination is usually diagnostic, and all views should be obtained. In STBs abnormalities are usually only detected in DL-PaMO and LM images and a skyline image of the distal row of carpal bones. All common osteochondral fragment locations should be carefully evaluated.

Fig. 38-4 • Dorsal 45° lateral-palmaromedial oblique radiographic image of a Thoroughbred racehorse with a typical small, displaced, distal radial carpal osteochondral fragment (*large arrow*), the most common small osteochondral fragment. The presence of enthesioid new bone formation (*small arrows*) at the joint capsule attachment indicates that damage of the radial carpal bone is chronic.

Fragments involving the distal aspect of the radial carpal bone are most visible on a DL-PaMO image and can vary in size, can be displaced or nondisplaced, and may extend to the level of the joint capsule attachment ([Figure 38-4](#)). Osteochondral fragments involving the third carpal bone most commonly affect the radial fossa and can be seen on the DL-PaMO, LM, and skyline images ([Figure 38-5](#)). Small osteochondral fragments involve only the middle carpal joint surface and usually break out dorsally, near the joint capsule attachment on the third carpal bone. It is important to differentiate small osteochondral fragments from frontal or sagittal slab fractures. Third carpal bone osteochondral fragments can be singular or numerous, involve only the radial or intermediate (rare) fossa or both, can be complete or incomplete, or can involve the medial (most common) or lateral corners of the bone. Medial corner fragments of the third carpal bone may resemble subchondral lucency and sagittal slab fracture, so other views must be carefully interpreted. Authentic sagittal slab fractures must be confirmed using a DM-PaLO image. Osteochondral fragments of the distal, lateral aspect of the radius are the largest of the small osteochondral fragments and are often bipartite. The large dorsal fragment is separated from the parent radius by a small separate fragment in the interposed trough ([Figure 38-6](#)). The large dorsal fragment can extend proximal to the joint capsule attachment on the distal lateral aspect of the radius. Concomitant osteochondral fragments frequently involve the proximal medial aspect of the intermediate carpal bone. Osteochondral fragments of the proximal aspect of the intermediate carpal bone may occur alone or in combination with osteochondral fragments of the distal lateral aspect of the radius ([Figure 38-7](#)). Other, less common osteochondral fragments do occur alone but usually in combination with

Fig. 38-5 • Dorsolateral-palmaromedial oblique xeroradiographic (**A**) and skyline radiographic (**B**) images of a horse with a third carpal bone small osteochondral fragment. The osteochondral fragment (*arrowheads*) breaks out of the dorsal aspect of the third carpal bone in the dorsolateral-palmaromedial oblique image, confirmation that it does not span both articular surfaces of the third carpal bone.

other osteochondral fragments. Evidence of OA such as enthesophytes and marginal osteophytes may be present (see [Figure 38-4](#)). Sclerosis of the third carpal bone is common in horses with osteochondral fragments of the third and radial carpal bones. Mild sclerosis is a normal adaptive response to training, and the presence of sclerosis as a solitary finding is not diagnostic of carpal lameness. Degree of sclerotic change is important, because in my experience a positive correlation exists between the degree of the third carpal bone sclerosis and the extent of cartilage damage on the third and radial carpal bones. However, a radiological study showed no significant relationship between degree of increased radiopacity and prognosis,⁴⁰ and although there was a continuous increase in the density of the third carpal bone in STB trotters in race training, increased radiopacity was of limited value in predicting carpal lameness.⁴¹ More recently, however, carpal lameness was more likely in STBs with higher grades of third carpal bone increased radiopacity.⁴²

Scintigraphic examination is an excellent method to diagnose incomplete or occult osteochondral fragments

Fig. 38-6 • **A**, Dorsal 45° medial-palmarolateral oblique radiographic image of a right carpus showing typical distal lateral radius small osteochondral fragment (*arrow*) in a Thoroughbred. **B**, Intraoperative photograph (dorsal is to the left; proximal is up) shows large dorsal fragment (*arrows*) separated from the parent radius by a small, interposed wedge-shaped fragment (*arrowheads*).

Fig. 38-7 • Dorsomedial-palmarolateral oblique radiographic image of a typical osteochondral fragment of the proximal aspect of the intermediate carpal bone. These fragments often appear in combination with osteochondral fragments of the distal lateral aspect of the radius and vary in size, but they generally occur slightly more medially than those of the distal, lateral aspect of the radius.

and to evaluate other sites of stress-related subchondral bone injury in the involved or contralateral carpus. Focal IRU on one side of a joint seen in several scintigraphic images, including a flexed dorsal image, can help pinpoint exact location of osteochondral fragments.

Management

The ideal treatment is surgical removal of osteochondral fragments, because unstable surfaces and fragment movement predispose to additional synovitis and development of osteoarthritis (see Figure 23-7). Fragments left in place to heal in displaced fashion cause uneven joint surfaces and are prone to refracture. Arthroscopic examination also allows evaluation and grading of cartilage damage and intercarpal ligament integrity and identification of occult fragments. However, factors such as economic value, racing class, and time of year relative to upcoming races and location of osteochondral fragments are relevant. Horses not worthy of arthroscopic surgery are managed with short-term rest and intraarticular injections of hyaluronan and corticosteroids, or they are given 3 to 6 months of rest. When conservative management procedures are used, fractures develop fibrous unions and become stable, but they are usually displaced and may resemble marginal osteophytes when healed. Many horses that are managed conservatively, especially those with fractures in the antebrachiocarpal joint, return to racing successfully, but recurrence of osteochondral fragments and development of OA are likely. It is difficult to convince owners and trainers to give horses long-term (>6 months) rest. However, rest, with or without arthroscopic surgery, is critical, not only for healing of incomplete fractures or, if osteochondral fragments have been removed, the fracture site, but also for healing of the surrounding cartilage and subchondral bone. Horses with incomplete osteochondral fragments are candidates for conservative management, but if horses are not given adequate time for fracture healing, recurrence is likely (Figure 38-8). Alternatively, I have recommended arthroscopic surgery and fragment removal in horses with incomplete fractures if I know the client will not opt for long-term rest without surgical intervention. Although

Fig. 38-8 • A, Dorsoproximal-dorsodistal (skyline) radiographic image of the distal row of carpal bones of a 2-year-old Standardbred colt with an incomplete osteochondral fragment of the third carpal bone. In this image there is predominantly dense increased radiopacity of the radial fossa, and the faint fracture is difficult to identify (*arrowheads*). **B,** Seven months later, when the horse was 3 years old, lameness and fracture recurred. The horse had been given inadequate rest to allow the fracture to heal completely.

carpal lameness may recur, at least the original osteochondral fragment will not refracture. During arthroscopic surgery, cartilage damage is graded as mild, moderate, severe, or global, and prognosis is inversely proportional to the extent of damage—a clinical finding substantiated in studies in STB, TB, and QH racehorses^{36,39} (see Figures 23-4 and 23-7, and Figure 38-1). During arthroscopic surgery, the osteochondral fragment(s) are removed and the surrounding cartilage and bone are curetted, depending on the amount of damage seen. If partial thickness cartilage damage is seen and damage does not extend into subchondral bone past the zone of calcified cartilage, then microfracture can be performed (see Chapter 23). Damage on apposing surfaces is common, and occult osteochondral fragments are often found there or at distant locations. Bilateral carpal arthroscopic surgery is commonly performed in all racing breeds, and in the TB and QH it may be necessary to evaluate all major joints.

After arthroscopic surgery horses are given a progressively increasing exercise program, the length of which depends on severity of damage and location of osteochondral fragments. For instance, in TB racehorses with osteochondral fragments of the distal, lateral aspect of the radius and the proximal aspect of the intermediate carpal bone, I recommend 2 weeks of stall rest, followed by 4 weeks of stall rest with hand walking (or walking in a caged walker), followed by 2 to 4 weeks of turnout or swimming physiotherapy. Lameness is less pronounced initially, and horses appear able to return to work earlier when osteochondral fragments involve the antebrachicarpal joint rather than the middle carpal joint. In horses with routine distal radial carpal bone and proximal third carpal bone fragments, I recommend 4 weeks of stall rest, followed by 4 weeks of

stall rest with hand walking, followed by 8 weeks of turnout or swimming physiotherapy. In horses with numerous fragments and severe or global cartilage damage, I recommend 4 to 6 months of total rest.

After arthroscopic surgery I recommend the use of intraarticular injections of hyaluronan at 14 and 28 days in horses with mild or moderate cartilage damage, and a series of intraarticular PSGAG injections at 3, 5, and 7 weeks after surgery. I recommend intramuscular administration of PSGAGs once weekly for 8 weeks, beginning 14 days after surgery. Little concrete evidence shows that any form or combination of intraarticular therapy is of long-term benefit for cartilage healing after surgery, although antiinflammatory effects are likely mildly beneficial. Short-term benefit of several intraarticular or parenterally administered products evaluated in an osteochondral fragment model has been shown (see Chapter 84).

Cartilage resurfacing techniques have been used experimentally and in a limited number of horses with osteochondral fragments and OA (see Chapters 23, 63, and 84). Cell-based techniques such as injection of cloned chondrocytes in autogenous fibrin loaded with growth factors appear promising. Microfracture of calcified cartilage appears promising in experimental trials, but seeing horses with partial-thickness cartilage damage is unusual. Subchondral bone is usually already exposed, obviating the need to use this.

Prognosis depends on several factors, including type and age of horse, racing class, limb(s) affected, number and location of osteochondral fragment(s), and amount of cartilage damage. Intuitively, a better prognosis would be expected in the STB than the TB and QH, because load is better shared by the hindlimbs and gait allows compensation by a lateral or diagonal limb. However, in STBs osteochondral fragments often develop later in the nonadaptive remodeling process, when OA is already well beyond that in TBs with comparable lesions. In most racehorses any damage of the third carpal bone is a major limiting factor in prognosis, and because osteochondral fragments of the third carpal bone are common in STBs, overall prognosis for STBs might be expected to be less favorable than for TBs and QHs. The prognosis for horses with lesions in the antebrachicarpal joint is better than for those in the middle carpal joint, and because osteochondral fragments occur with similar frequency in both joints in TBs and QHs, the overall prognosis is better. The prognosis for return to racing is good to excellent, but the likelihood of racing at the preinjury level is inversely proportional to the degree of cartilage damage. Seventy-four percent of STBs with osteochondral fragments returned to racing after arthroscopic surgery, but only 61% raced at or above the preinjury level. Pacers were more likely than trotters to start a race and to have five starts before and after injury.³⁶ Kinematic studies show that the pace may slow forelimb fatigue and reduce forelimb load.⁴³ Median earnings per start decreased significantly after injury and arthroscopic surgery, but horses went significantly faster after surgery.³⁶

Of 445 TB and QH racehorses, 303 (68%) raced at a level equal to or better than the preinjury level, but when grouped according to cartilage damage, only 53% of horses with the most severe cartilage damage raced at these levels. Eleven percent of horses had decreased performance and had carpal lameness, 6% developed additional

osteochondral fragments, and 2% developed collapsing slab fractures while racing.³⁶ Prognosis was worse for horses with osteochondral fragments of the third carpal bone.

Palmar Carpal Osteochondral Fragments

Osteochondral fragments can occur in the palmar aspect of the carpus and can result from a single-event injury or can be associated with other osteochondral fragments in the dorsal aspect of the carpal joints. Trauma may result from falling, hitting a fence, or landing with subsequent hyperextension of the carpus or falling when the carpus is flexed (hyperflexion). Palmar carpal injury is one of the more common catastrophic injuries occurring in horses during recovery from general anesthesia (Figure 38-9, A). Palmar carpal injury after general anesthesia can be career-limiting or career-ending and often leads to severe OA of the involved carpal joints. In horses that sustain palmar carpal fragments as a result of a traumatic event, osteochondral fragments usually involve the palmar aspect of the radial and intermediate carpal bones and the articular surface of the accessory carpal bone but can involve any of the carpal bones, can be singular or numerous, and occur medially and laterally. Articular osteochondral fragments of the accessory carpal bone are usually comminuted and involve at least two or three pieces.

In horses with known chronic osteochondral fragments in the dorsal aspect of the carpus and those with OA, radiographs occasionally reveal what appear to be small fragments or mineralization in the palmarolateral or palmaromedial aspects of the middle carpal joint (see Figure 38-9, B). It was once thought that radiopacities in the palmar aspect of the middle carpal joint were areas of

dystrophic mineralization after corticosteroid injections, but it is now known these are most likely small fragments that migrate from the dorsal to the palmar aspect of the joint and occur when training and racing continues in horses with existing osteochondral fragments, which then become macerated. When the condition is observed, cartilage damage is usually extensive, and prognosis is guarded. In a study of 31 racehorses with palmar carpal osteochondral fragments, only 48% of horses returned to racing and earned money, and only 32% had five or more race starts after injury.²² Horses with numerous fragments had significantly lower earnings and lower performance indices after surgery than those with one fragment, and those with fragments smaller than 3 mm diameter were significantly less likely to return to racing than those with larger fragments.²² Palmar carpal fragments were most commonly seen in the palmarolateral pouch of the middle carpal joint and in 24 horses were associated with coexistent osteochondral fragmentation in the dorsal aspect of the joint.²² Seven horses had palmar carpal fragments without associated dorsal fragmentation, and in six of these seven horses fragments involved the palmar aspect of the antebrachicarpal joint (all involved the proximal aspect of the radial carpal bone).²² It has been suggested that fragment migration from the dorsal to the palmar aspect of the middle carpal joint occurs because of medial palmar intercarpal ligament injury, an association that I have not found true. No association was found between palmar carpal fragment size or number and medial palmar intercarpal ligament injury.²²

Lameness is acute in onset, with effusion of the middle carpal or antebrachicarpal joints. Often the response to static flexion of the carpus is profound. Careful

Fig. 38-9 • **A**, Dorsal 45° medial-palmarolateral digital radiographic image of the left carpus of a horse sustaining a comminuted palmar carpal fracture of the radial carpal bone (arrows) and intermediate carpal bones during recovery from general anesthesia. Because of severe lameness this horse was euthanized. **B**, Lateromedial digital radiographic image of a racehorse with palmar carpal osteochondral fragments (large arrow) located in the palmarolateral pouch of the middle carpal joint. Fragments have migrated from a primary site of osteochondral fragmentation, the distal dorsal aspect of the radial carpal bone (small arrow). (**A** courtesy David Levine and Eric Parente, Kennett Square, Pennsylvania, United States. **B** courtesy of Liberty Getman, Kennett Square, Pennsylvania, United States.)

interpretation of radiographs is necessary to confirm the presence of osteochondral fragments, locate precisely the parent bone from which the osteochondral fragment arose, and determine the number of fragments. The clinician should recognize that osteochondral fragments in the palmar aspect of the carpus may represent only one aspect of more global damage to the joint(s). Any evidence of fragmentation dorsally, or active OA if trauma occurred at least 10 to 14 days before radiographic examination, is a poor prognostic indicator, because this reflects substantial subchondral bone and cartilage injury dorsally. OA and chronic lameness are inevitable, particularly in horses with palmar carpal injury sustained while jumping or during recovery from general anesthesia. Palmar osteochondral fragments can be removed using arthroscopic surgery or arthrotomy,⁴⁴ but access can be difficult. Recent studies have refined the surgical approaches and anatomy of the palmar pouches of the carpal joints and the value of arthroscopic examination.^{16,21,22} The palmarolateral pouch of the antebrachio-carpal joint is large, and osteochondral fragments involving the accessory and intermediate carpal bones can be removed from this approach. When removing osteochondral fragments from the palmaromedial or the palmarolateral aspect of the middle carpal joint, both portals must be made within a small joint pouch, making triangulation difficult. Prognosis for future soundness is guarded to fair for racehorses (see earlier). In nonracehorses, prognosis for horses with single fragments without substantial OA is fair, but it is guarded to poor in those

with substantial instability or bone and cartilage damage at more distant sites.

Large Osteochondral Fragments: Slab Fractures

Slab fractures are defined as fractures that involve a proximal and distal articular surface and thus traverse the entire depth (proximal-distal direction) of the bone. Size and involvement of two articular surfaces differentiate these fractures from small osteochondral fragments. Slab fractures of the third carpal bone are by far the most common form of large osteochondral fragments in the carpus, but slab fractures of the radial, fourth, and intermediate carpal bones occasionally occur. A combination of radial and third carpal bone slab fractures occurs in TB racehorses and may lead to instability and carpal collapse. In most instances, slab fractures develop as a terminal event in the cascade of maladaptive or nonadaptive remodeling changes leading to sclerosis, biomechanical weakness, and subsequent fracture. When slab fractures occur in unusual locations, the possibility of single-event injury must be considered. Slab fractures occur almost exclusively in racehorses.

Frontal (Dorsal) Slab Fractures of the Third Carpal Bone

The most common large osteochondral fragment in the carpus is a slab fracture of the third carpal bone in the frontal (dorsal) plane. A frontal slab fracture of the third carpal bone usually involves the radial fossa, but fractures of the intermediate fossa alone or in combination with fracture of the radial fossa do occur (Figures 38-10 and

Fig. 38-10 • A, Standing lateromedial digital radiographic image (dorsal is to the left) showing a complete, mildly displaced frontal slab fracture of the radial fossa of the third carpal bone (*arrows*) in a 3-year-old Thoroughbred racehorse. The fracture line traverses the entire depth of the third carpal bone involving the middle carpal and carpometacarpal joints. Displacement is best seen in this radiographic image. **B,** Dorsoproximal-dorsodistal (skyline) digital radiographic image of the distal row of carpal bones showing the frontal slab fracture of the radial fossa of the third carpal bone (medial is left and palmar is uppermost). The slab fracture traverses the entire radial fossa (*arrow*). Interposed between the fracture line and the parent third carpal bone is a wedge-shaped osteochondral fragment (*arrowheads*) that is generally removed before repair. **C,** The frontal slab fracture has been repaired using a single 3.5-mm bone screw placed in lag fashion in the center of the fracture fragment using arthroscopic guidance. The wedge-shaped fragment seen in the preoperative view (**B**) has been removed, and there is good anatomical alignment of the repair.

Fig. 38-11 • **A**, Dorsal 45° medial-palmarolateral oblique digital radiographic image showing a displaced frontal slab fracture of the intermediate fossa of the third carpal bone (*arrow*). **B**, Dorsoproximal-dorsodistal digital radiographic image of the distal row of carpal bones (medial is to the left and palmar is uppermost) showing a comminuted frontal slab fracture of the third carpal bone involving the radial (*large arrow at fracture line*) and intermediate (*arrowheads at fracture line*) fossae.

38-11). Frontal slab fractures of the third carpal bone involving the radial fossa vary in size and can involve the entire medial-to-lateral width of the fossa, or any portion of it, and range from the common size of 8 to 10 mm in the dorsal-to-palmar direction up to 20 to 25 mm. These latter, large fragments cannot be seen on a skyline radiographic image, extend across the entire medial-to-lateral width of the third carpal bone involving both fossae, and are L shaped (Figure 38-12).

Lameness in horses with a frontal slab fracture is acute and severe and is generally worse than in those with small osteochondral fragments, but chronic, subtle prodromal lameness may have been present. A previous history of small osteochondral fragments and arthroscopic surgery is common. Lameness may be less than expected in horses recently injected with corticosteroids and in those with bilateral frontal slab fractures of the third carpal bone. Clinical signs such as heat, effusion, and response to static

and dynamic flexion are pronounced, and horses are usually lame at the walk. Horses with non-weight-bearing lameness may have unstable carpi and should be evaluated carefully for collapse from comminuted fractures. The contralateral carpus should always be evaluated and palpation should be complete to uncover compensatory lameness problems. In TB racehorses in North America the right third carpal bone is affected more commonly than the left,⁴⁵ but in STBs the distribution between right and left is similar.⁴⁶

Frontal slab fractures of the third carpal bone are usually obvious radiologically. If they involve the radial fossa, fractures are best seen on the LM, flexed LM, and DL-PaMO images and a skyline image. Because frontal slab fractures of the third carpal bone by definition involve the middle carpal and carpometacarpal joint surfaces, if a fracture line breaks out dorsally before reaching the carpometacarpal joint, the fragment is not a true slab fracture. This is important when determining a management plan. A frontal slab fracture of the third carpal bone can be incomplete, complete but nondisplaced, or complete and displaced and may be associated with other small osteochondral fragments. Degree of displacement is worse on a standing LM image, but when the carpus is flexed, the fracture returns to near normal alignment. Flexion is a useful maneuver during reduction. In most instances a triangular, wedge-shaped fragment appears in the trough between the slab fracture fragment and the parent bone, and this accounts for the appearance of many fracture lines in a skyline view (see Figure 38-10, *B*). Careful examination of the overlying radial carpal bone is required in TB racehorses, because concomitant slab fracture of the radial carpal bone can accompany a frontal slab fracture of the third carpal bone.

Management depends on several factors, including the horse's value, age, racing class, presence of other lameness problems, and specifically whether the frontal slab fracture of the third carpal bone is incomplete, displaced, or comminuted. Long-term rest (6 months) is successful in horses with incomplete or complete nondisplaced fractures. However, surgical fixation can help preserve articular surfaces by preventing displacement. Frontal slab fracture fragments that are thin (<5 mm in the dorsal-to-palmar direction) can be removed using arthroscopic surgery or conventional arthrotomy techniques or, if the articular surface is intact, can be repaired. Arthroscopic techniques are preferred when possible, and the technique remains largely unchanged since originally described.⁴⁷ Surgical removal of small frontal slab fractures of the third carpal bone can be difficult using arthroscopic techniques and can leave a large defect radiologically but is successful. Horses with large frontal slab fragments that are displaced are usually managed with arthroscopic surgery and internal fixation, using one or two cortex screws placed in lag fashion. Either 3.5- or 4.5-mm screws can be used, but I prefer using one or two 3.5-mm screws because the screw heads are smaller and countersinking in the dorsal aspect of the third carpal bone is not necessary. Horses with large frontal fractures of the radial fossa, those with comminuted fractures involving both the radial and intermediate fossae (see Figure 38-11), and those in which fracture fragments cannot be adequately reduced should be repaired with 4.5-mm screws, because 3.5-mm screws can sometimes break. Use of needles and intraoperative radiographs to position and guide screw insertion accurately is preferred.⁴⁵

Fig. 38-12 • This pacer had an L-shaped fracture of the third carpal bone that involved a sagittal and frontal component. **A**, The initial intraoperative photograph shows the sagittal component (*arrows*) and crushed medial aspect of the third carpal bone. **B**, This area was debrided, and the fracture healed without internal fixation. The sagittal component of the fracture appears palmar to the defect. **C**, True proximal-to-distal radiographic image of a trotter obtained at necropsy shows that the large slab fracture of the third carpal bone has frontal and sagittal components. C2, Second carpal bone; C3, third carpal bone; C4, fourth carpal bone; RC, radial carpal bone.

A single bone screw provides adequate fixation in horses with most frontal slab fractures of the third carpal bone involving only the radial fossa, because capsular attachments maintain rotational stability. The fracture line is debrided, often before screw placement, and the wedge-shaped trough fragment is removed, leaving a gap at the fracture line. Loose cartilage is curetted, cartilage damage is graded, and other small osteochondral fragments are removed if present. Alternatively the proximal articular surface of the fragment may be removed, with repair of the distal aspect, leaving the portion of the fragment with capsular attachments intact. Occasionally, additional slab fractures of the third or radial carpal bones are found and repaired. In horses with more than one slab fracture, a Robert Jones bandage or cast is used for recovery from general anesthesia. In TB racehorses with a frontal slab fracture of the third carpal bone, an ominous defect in the

articular cartilage of the radial carpal bone is often seen, caused by the incongruent apposing surface of the third carpal bone, but in most horses subchondral bone fracture is not present. Horses are typically given stall rest for 4 weeks, followed by stall rest with hand walking for 8 weeks, followed by turnout in a small paddock for 2 to 3 months before beginning race training. Recommendations for intraarticular therapy are similar to those in horses with small osteochondral fragments.

In a large retrospective study of TB and STB racehorses with a frontal slab fracture of the third carpal bone, the radial fossa was involved in 87% of horses, and females of both breeds were less likely to race after injury and surgery, but treatment and fracture characteristics had no effect on outcome.⁴⁶ Fracture characteristics such as size and degree of displacement did influence treatment selection, so thin frontal slab fractures of the third carpal bone were removed,

displaced fractures were repaired, and horses with incomplete or nondisplaced frontal slab fracture of the third carpal bone were managed conservatively.⁴⁶ All STBs that had raced before surgery also raced after surgery, and overall 77% raced after surgery. Sixty-five percent of TBs with frontal slab fractures of the third carpal bone raced after surgery, and although earnings per start decreased in both breeds, the decrease was more pronounced in TBs.⁴⁶ In another study, 67% of TBs with a frontal slab fracture of the third carpal bone raced at least once after surgery, but the mean claiming value in horses decreased significantly.⁴⁵ In a study in which lag screw fixation was used in horses with incomplete frontal plane fractures of the radial facet of the third carpal bone, 69% of horses were considered to have successful outcomes, and there was no difference in racing longevity or ability after surgery between principles and age-, sex-, and sire-matched controls.⁴⁸

Sagittal Slab Fractures of the Third Carpal Bone

Sagittal slab fractures of the third carpal bone are much less common than frontal slab fractures, usually involve the medial aspect of the radial fossa (see [Figures 38-12](#) and [38-13](#)), and occur in a direction parallel to the articulation between the second and third carpal bones. However, sagittal slab fractures of the third carpal bone can occur in the intermediate fossa, and fractures can be bilateral. Authentic

sagittal slab fractures of the third carpal bone involve both articular surfaces of the bone and can be best seen radiologically in skyline and DM-PaLO images. Sagittal slab fractures of the third carpal bone must be differentiated from corner fractures, subchondral lucency, and other crushing-type injuries that occur in the radial fossa. Clinical signs associated with sagittal slab fractures of the third carpal bone are similar to those of other osteochondral fragments but are usually less severe than a frontal slab fracture of the bone. Lameness is usually prominent, but in horses with bilateral fracture or substantial OA or osteochondral fragments in the contralateral carpus, diagnostic analgesia may be required. Often horses have a prominent history of chronic carpal lameness before acute lameness develops. Of 32 racehorses with sagittal slab fracture of the third carpal bone, 19 were TBs, 11 were STBs, and 2 were Arabian racehorses, and fractures were found in the right forelimb (19), left forelimb (12), and bilaterally in one horse.⁴⁹ Overall, 22 (69%) horses raced after treatment, all seven horses treated with interfragmentary compression raced, and horses that underwent interfragmentary compression had significantly higher earnings per start than those treated without surgery.⁴⁹ Eight of nine horses managed with arthroscopic debridement raced, but only 7 of 16 horses managed conservatively raced.⁴⁹

Conservative management was recommended, but only 7 of 12 horses with a sagittal slab fracture of the third carpal bone managed conservatively raced.⁵⁰ Fracture healing takes extensive time, and a chronic nonunion often develops (see [Figure 38-13, B](#)). Horses can be sound enough to race with chronic nonunion fractures, but this is undesirable. I have seen one STB and one TB racehorse with bilateral lateral, nonunion sagittal slab fractures of the third carpal bone racing successfully, but with conservative management comes a risk of chronic high-speed lameness, worse if fracture involves the right forelimb, and horses drop substantially in racing class. If any doubt exists about the nature of a lesion affecting the medial aspect of the third carpal bone, arthroscopic examination can be performed to formulate a surgical plan. If an authentic sagittal slab fracture of the third carpal bone does not exist, but medial corner osteochondral fragments, necrotic subchondral bone, or other crush-type injuries are found, a combination of fragment removal and curettage is performed. I currently recommend surgical management for most horses with sagittal slab fractures of the third carpal bone. To repair a fracture, I prefer a direct view provided by arthrotomy, because positioning a screw perpendicular to the fracture line using arthroscopic surgery and stereotactic techniques is difficult and because the fracture is closely associated with the second carpal bone. A single 3.5-mm screw is placed in lag fashion. Alternatively, arthroscopic evaluation and debridement result in a better outcome than does conservative management.⁴⁹ Evaluating the joint arthroscopically and then formulating a management plan is a reasonable approach, but certainly surgical management is preferred over rest alone. Management after surgery is similar to that described for horses with frontal slab fractures of the third carpal bone.

Slab Fractures of Other Carpal Bones

Slab fractures of carpal bones other than the third are unusual. Whenever slab fractures of the radial carpal bone

Fig. 38-13 • Initial (**A**) and 8-month follow-up (**B**) skyline radiographic images of the third carpal bone showing a sagittal slab fracture (*arrows*) that failed to heal and became a nonunion (**B**). This Standardbred trained and raced with the nonunion fracture but dropped substantially in class. Results such as this have prompted me to manage sagittal slab fractures of the third carpal bone surgically.

or other unusual slab fractures are discovered, all radiographic images should be evaluated carefully. CT was shown to be valuable in identifying fracture lines and comminution not seen using radiography.¹⁴ Slab fractures of the radial carpal bone can occur independent of or in combination with frontal slab fracture of the third carpal bone. When frontal slab fractures of the radial and third carpal bones occur simultaneously and carpal instability results, the fracture is called a *comminuted carpal fracture*. Repairing both bones by placing numerous screws using arthroscopic surgery may be possible. A sleeve or full-limb fiberglass cast is placed, and an assisted recovery from general anesthesia is recommended.

Slab fractures of the intermediate, fourth, and ulnar carpal bones occur rarely. In five horses with intermediate and fourth carpal bone slab fractures, outcome was poor because of delay in diagnosis, and four horses were only pasture sound.⁵¹ Surgical repair should proceed as early as possible, but prognosis is limited by cartilage damage and other osteochondral fragments.

Subchondral Lucency of the Third Carpal Bone

Subchondral lucency of the third carpal bone⁵² is an unusual condition occurring most commonly in STB racehorses, although it is occasionally seen in the TB racehorse, and is seen radiologically as single or multiple central areas of bone loss in the radial fossa of the third carpal bone (Figure 38-14). Overall, I am seeing fewer STB racehorses with this lesion. Earlier recognition and intervention may be credited. Lesions can be seen in a DL-PaMO image in horses with advanced subchondral lucency of the third carpal bone. Mild-to-severe sclerosis may surround radiolucent defects,⁵² but in one study no relationship was found between radiolucency of the third carpal bone and increased radiopacity.⁴⁰ The lesion was more common in the right carpus, and, although pacers predominated, distribution was similar to the racing population in the United States.⁵² Pathogenesis is identical to that described for OA, osteochondral fragments, and slab fractures of the third carpal bone, but in horses with subchondral lucency of the third carpal bone, necrosis of subchondral bone causes table surface collapse rather than osteochondral fragments or slab fractures involving the dorsal margin. Subchondral lucency of the third carpal bone is not a disease of young racehorses, because the mean age in STBs was 4.1 years (range, 3 to 7 years) and chronic stress-related subchondral bone injury is required.

There are prodromal clinical signs of mild carpal lameness and usually a history of the administration of numerous intraarticular injections before onset of acute lameness, usually graded from 2 to 4 on a 5-point scale. Heat, effusion, and a positive response to flexion may be absent, and diagnostic analgesia is usually required to confirm diagnosis. The results of initial radiological evaluation may be equivocal, and follow-up radiographic and scintigraphic examinations can help pinpoint subchondral lucency of the third carpal bone. Focal areas of IRU in the radial fossa of the third carpal bone similar to that seen with frontal or sagittal slab fracture are seen.

Surgical debridement is the treatment of choice (see Figure 38-14, B). During arthroscopic examination, soft crumbly necrotic subchondral bone and damaged overlying cartilage are found. In some horses only a small

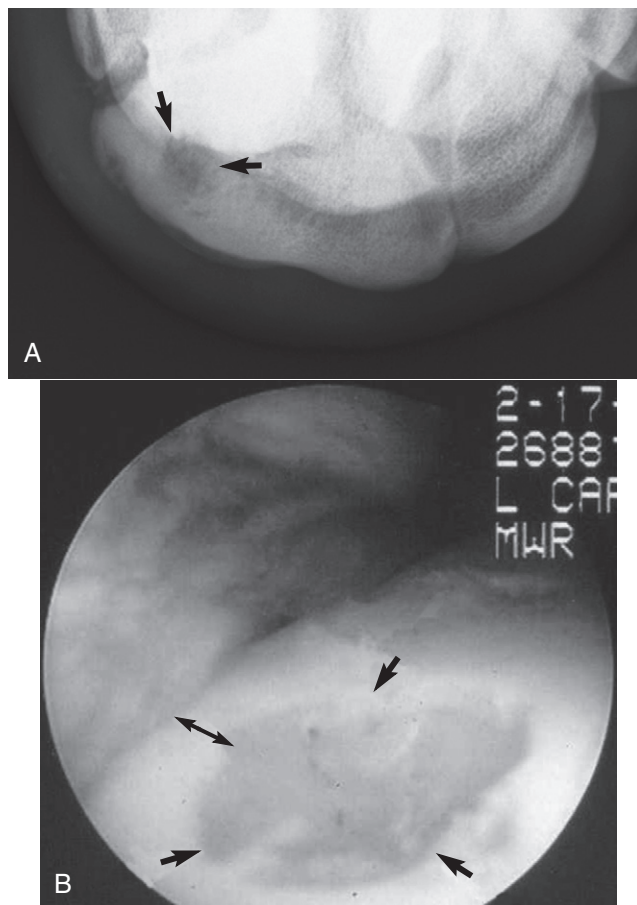

Fig. 38-14 • A, Dorsoproximal-dorsodistal (skyline) digital radiographic image of the left carpus of a Thoroughbred racehorse with subchondral lucency (arrows) of the radial fossa of the left third carpal bone (medial is to the left and palmar is uppermost). Subchondral lucency of the third carpal bone should be differentiated from other sagittal plane injury, such as sagittal slab fracture. This horse underwent arthroscopic debridement successfully. **B,** Intraoperative arthroscopic photograph of the left third carpal bone of a Standardbred racehorse that underwent successful debridement of subchondral lucency of the third carpal bone (dorsal is to the left and proximal is uppermost). Full-thickness cartilage damage and soft, crumbly subchondral bone were debrided (arrows), and the dorsal aspect (rim) of the third carpal bone was left intact (double-headed arrow). (A courtesy Dean Richardson, Kennett Square, Pennsylvania, United States.)

full-thickness cartilage defect can be probed, but deep extensive subchondral bone softening is later found, whereas in others, fibrin-filled, full-thickness defects resembling subchondral bone collapse or table surface fracture are found. The damaged tissue is curetted, and if the resulting lesion is smaller than 5 mm palmar to the dorsal margin of the third carpal bone, this rim is removed, creating a defect that resembles removal of an osteochondral fragment. If subchondral lucency of the third carpal bone lesions is deep within the third carpal bone, the dorsal margin is not removed. Cartilage resurfacing could be considered, but it is not necessary for a successful outcome.

Prognosis is excellent for return to racing, particularly in pacers, but horses drop in racing class. Prognosis for return to racing the next year is guarded in 3- or 4-year-old trotters, but some make useful older racehorses. Of nine

Fig. 38-15 • A, Non-weight-bearing dorsopalmar computed radiographic image obtained before surgery of the left carpus (lateral is to the right and proximal is uppermost) in an aged gelding riding horse that sustained a comminuted carpal fracture while turned out. Notice marked carpus valgus limb deformity caused by collapse of the lateral aspect of the middle carpal joint. There were comminuted fractures of the third and fourth carpal bones. **B,** Dorsopalmar digital radiographic image obtained 3 years after successful panarthrodesis of the carpus, showing complete fusion of the antebrachiocarpal, middle carpal, and carpometacarpal joints. Two broad dynamic compression plates and interfragmentary compression of the third carpal bone were used. Today, locking compression plates would likely be used, but successful arthrodesis was achieved with this fixation in conjunction with external coaptation with a fiberglass sleeve cast.

horses, eight returned to racing, but only six raced at the previous level.⁵²

Comminuted Fractures

Comminuted fractures are unusual, but they occur occasionally in TB and QH racehorses and other horses that sustain injury while turned out in a field. *Comminuted* in this sense refers to numerous fractures in more than one carpal bone. In STB racehorses, large, comminuted fractures of the third carpal bone can occur, but I have not seen a STB with a large osteochondral fracture involving more than one bone. The most common combination of fractures in TB and QH racehorses involves the third carpal bone and either the radial or intermediate carpal bone, or both. Carpal instability, most commonly carpus varus, is usually readily apparent if horses bear weight, but they are usually non-weight bearing. These injuries occur almost exclusively in racehorses, and often horses have chronic carpal lameness before injury, but fracture can occur in other types of horses without previous lameness during turnout exercise. Effusion and edema of surrounding soft tissues occurs. Diagnosis of comminuted fracture and instability is confirmed radiologically (Figure 38-15). If fractures involve only the distal row of carpal bones, instability is minimal and prognosis is better than if the middle carpal and antebrachiocarpal joints are involved. Consideration should be given for euthanasia if the horse is a gelding or

intact male with limited breeding potential. Conservative management using sleeve or full-limb casts, or a combination of splints with a Robert Jones bandage, may give support and provide comfort, but usually instability is pronounced, horses develop extensive cast sores, and they are at profound risk to develop laminitis in the contralateral limb. Severe OA, collapse, and angular limb deformity generally result in an unacceptable outcome in horses managed conservatively. Surgical management using carpal arthrodesis is the treatment of choice.

Carpal Arthrodesis

Arthrodesis is indicated when horses have comminuted carpal fractures and instability, when they have severe lameness and OA of one or more carpal joints, or when OA is severe with collapse and angular deformity of the carpus. Partial (intercarpal) carpal arthrodesis involves fusing the middle carpal and carpometacarpal joints using bone plates applied to the proximal row of carpal bones and the McIII. Pancarpal arthrodesis involves bridging the entire carpus with bone plates applied to the distal radius, both rows of carpal bones, and the McIII, fusing all three joints. Two plates, either dynamic compression plates or, more recently, locking compression plates,^{53,54} are used for either technique, and in one study allografts were used to provide axial support in some horses with collapsed carpi undergoing pancarpal arthrodesis. In one horse, I successfully

used acrylic to create an artificial fourth carpal bone to maintain axial stability, in addition to two dynamic compression plates and interfragmentary repair of fractures (see [Figure 38-15](#)). Overall, prognosis for salvage is good, but complications included infection and contralateral laminitis. Of 36 horses undergoing carpal arthrodesis, 30 (83%) survived 3 months, and 24 (67%) survived at least 9 months after surgery.⁵⁵ Prognosis was similar between horses undergoing pancarpal and partial carpal arthrodesis.^{55,56}

Accessory Carpal Bone Fractures

Fracture of the accessory carpal bone results from trauma, such as a fall while jumping, a hyperextension injury when landing, or an accident while turned out. Acute, severe lameness and swelling involve the palmar aspect of the carpus. Horses have severe pain during carpal flexion. Carpal tenosynovitis may occur acutely, but it is difficult to differentiate from diffuse swelling. Pronounced lameness lasts for several days, but horses are rarely non-weight bearing, and swelling resolves in 2 to 3 weeks. Horses with a chronic fracture may have little to no swelling, and diagnosis may be difficult unless carpal tenosynovitis is present, because the lameness is not typical of carpal pain.

The most common fracture of the accessory carpal bone is a vertical slab fracture that involves the palmar aspect of the bone in the frontal (dorsal) plane ([Figure 38-16](#)). Most fragments are simple, but small fragments at the proximal aspect of the fracture may occur. Fractures can be incomplete, but most are complete with mild displacement. Gross

Fig. 38-16 • A lateromedial radiographic image of a horse with a failed attempt at surgical management of a frontal slab fracture of the accessory carpal bone. These fractures are best managed conservatively without attempting repairs such as this one.

displacement and large comminuted fragments are unusual. Articular fractures were discussed previously (see page 439).

Conservative management of horses with nonarticular fractures of the accessory carpal bone is recommended. The forces on the accessory carpal bone are substantial and result in failure of screw fixation, chronic instability, implant loosening, and osteitis (see [Figure 38-16](#)). Surgical fixation using the tension band principle may be successful, but I have not attempted repair because prognosis is favorable with conservative management. Horses are given NSAIDs, and a heavy full-limb cotton bandage is applied. Horses are given stall rest for 8 weeks, followed by stall rest with hand walking for 8 weeks, followed by walking with a rider up for 8 weeks. Radiographs most often reveal bony proliferative changes and fibrous rather than bony union of the fracture. Even with fibrous union, horses are usually serviceably sound. Prognosis for TB racehorses appears to be worse than for field hunters, jumpers, and other horses that may be able to perform with a mild gait restriction from chronic fibrosis. Carpal canal syndrome and carpal tenosynovitis may result (see Chapter 75).

Osteochondrosis

Osteochondrosis of the carpus is rare. In a radiological study of yearling TBs, 0.4% had either radiological changes associated with osteochondritis dissecans (OCD) or a subchondral bone cyst, other than that seen involving the distal aspect of the ulnar carpal bone (see later).⁵⁷ In experimental studies extensive cartilage lesions histologically similar to those in naturally occurring OCD have been produced. Rarely, radiographs of yearlings before or after public sales reveal rounded osteochondral fragments, usually involving the distal medial aspect of the radius or the distal medial aspect of the radial carpal bone or proximal aspect of the third carpal bone. These fragments appear as solitary osteochondral fragments and do not have associated marginal osteophytes or enthesophytes, unlike osteochondral fragments caused by trauma at a young age. At the time of surgery these unusual fragments appear intercalated in dense joint capsule attachments, are rounded, and often have a smooth defect in the distal aspect of the radius or third carpal bone, apparently the origin of the fragment. Whether these fragments represent a form of OCD or old trauma is not known, but they appear similar to forms of OCD found elsewhere.

Osseous Cystlike Lesions

Osseous cystlike lesions do occur in the carpus. Those of the ulnar carpal bone are common, appear to be incidental radiological findings, are usually nonarticular, and have sclerotic borders. Often, small bony fragments can be seen within the radiolucent defect and can be misinterpreted as acute fractures, sometimes called *avulsion injury of the lateral palmar intercarpal ligament* (see later). Ulnar carpal bone radiolucent defects were the most common radiological abnormality found in a large study of TB yearlings.⁵⁷ Abnormalities of the distal aspect of the ulnar carpal bone were found in 20% of yearlings and were exclusively unilateral, and no negative association between this radiological change and racing performance was found.^{57,58} Incidental osseous cystlike lesions may also be seen in the second carpal bone, often in the presence of the first carpal bone, and also in the base (head) of the McII. Osseous

cystlike lesions of the radial carpal bone and distal aspect of the radius can cause lameness.⁵⁹ Effusion, heat, and a positive response to flexion are inconsistent, and diagnostic analgesia is usually necessary. Radiological signs may be obvious, but in some horses they are subtle, and scintigraphic examination is useful to pinpoint the area of modeling. In horses with an osseous cystlike lesion that communicates with an articular surface, I have performed debridement and curettage, but results have been unfavorable to fair at best. Alternatively, I have had good success using a combination of rest (4 to 6 months) and serial intraarticular injections (two or three) of hyaluronan and corticosteroids (40 mg methylprednisolone acetate) when cysts appear radiologically to communicate with a carpal joint (see Figure 39-4).

Osteochondromatosis

Osteochondromatosis is rare but has been seen in the carpometacarpal joint.⁶⁰ Progressive enlargement of the carpometacarpal joint and numerous unusual radiopacities were seen radiologically.⁶⁰ Arthroscopic examination of the carpometacarpal joint was possible, and osteochondral fragments were removed⁶⁰ (see Chapter 67).

Infectious Arthritis

See Chapter 65 for a discussion of infectious arthritis.

Other Fractures Involving the Carpus

Avulsion Fracture of the Third Metacarpal Bone Associated with the Origin of the Suspensory Ligament

See Chapter 37 for a discussion of avulsion fracture of the McIII associated with the origin of the SL (page 417).

Incomplete, Longitudinal Fracture of the Proximal Palmar Cortex of the Third Metacarpal Bone

See Chapter 37 for a discussion of incomplete, longitudinal fracture of the proximal palmar cortex of the McIII (page 413).

Dorsomedial Articular Fracture of the Proximal Aspect of the Third Metacarpal Bone

See Chapter 37 for a discussion of dorsomedial articular fracture of the proximal aspect of the McIII (page 416).

Fracture of the Proximal Aspect of the Second and Fourth Metacarpal Bones

See Chapter 37 for a discussion of the proximal aspect of the McII and the McIV (page 421).

Articular Fracture of the Distal Aspect of the Radius

Fractures of the distal aspect of the radius rarely involve the antebrachiocarpal joint. Complete or incomplete, displaced or nondisplaced fractures of the radius in the sagittal plane and resembling condylar fractures of the McIII or the third metatarsal bone can occur.⁶¹ Horses should be managed conservatively using full-limb bandages, NSAIDs, and absolute stall rest if fractures are nondisplaced. Some consideration should be given to cross-tying the horse for 3 to 6 weeks. Comminuted fractures of the radius, or those involving the distal radial physis and epiphysis that involve the antebrachiocarpal joint, should be repaired.

Soft Tissue Injuries of the Carpus and Carpal Region

Medial Palmar Intercarpal Ligament

Various degrees of tearing of the medial palmar intercarpal ligament have been observed during arthroscopic examination of horses with osteochondral fragments or OA and in some horses with occult carpal lameness (see Figure 23-4). The medial palmar intercarpal ligament has recently been the source of considerable study and supposition, but whether tearing of this ligament observed in horses with carpal disease is causative or simply results from other pathological conditions is not yet known. The anatomy of the medial palmar intercarpal ligament and the relationship between osteochondral fragments and the dorsomedial intercarpal ligament were previously discussed (see page 427).

Because tearing of the medial palmar intercarpal ligament is an observation during arthroscopic examination of the middle carpal joint and a diagnosis impossible currently to make before surgery, specific clinical signs cannot be described. Once MRI becomes more widely available, diagnosis in horses with occult carpal lameness suspected to originate from the medial palmar intercarpal ligament may be possible before arthroscopic examination. Tearing of the medial palmar intercarpal ligament was observed in 27 joints in 20 horses with carpal lameness.⁵ No correlation was found between tearing and severity of clinical signs. Joints with more medial palmar intercarpal ligament tearing had significantly *less* cartilage and subchondral bone damage, and an inverse relationship existed between the size and number of osteochondral fragments and ligament damage.⁵ Therefore, although tearing of the medial palmar intercarpal ligament occurred commonly in horses with middle carpal joint damage, tearing was not seen with severe subchondral bone damage, and what role damage plays in the development of joint disease remains questionable.

In my experience, tearing of the medial palmar intercarpal ligament is unusual without at least mild cartilage damage or osteochondral fragmentation, but I have seen a small number of horses in which the only identifiable lesion was tearing and hemorrhage of the frayed ends, resulting in hemarthrosis. Complete tearing of the medial palmar intercarpal ligament occurs more frequently in TB racehorses compared with STBs; partial tearing (fraying) of the medial palmar intercarpal ligament is quite common in STBs. In horses with a complete tear of the ligament, examining the palmar aspect of the middle carpal joint from the routine dorsal approach was possible. Rupture of the medial palmar intercarpal ligament has been seen in a small number of nonracehorse competition horses with pain localized to the middle carpal joint.⁶² No other lesion was identified during arthroscopic examination. I suspect tearing of the medial palmar intercarpal ligament in horses with confirmed carpal lameness, but in which scintigraphic and radiological findings are negative or equivocal, and in those with unexplained hemarthrosis of the middle carpal joint. Because horses that fall into this category are rare, prognosis is difficult to estimate.

Lateral Palmar Intercarpal Ligament

Avulsion injury at the origin of the lateral palmar intercarpal ligament on the ulnar carpal bone has been described

Fig. 38-17 • A, Delayed-phase scintigraphic images of a 3-year-old Thoroughbred colt with mild increased radiopharmaceutical uptake (IRU) in the medial aspect of the right radial carpal bone (arrow). There is normal radiopharmaceutical uptake in the region of the ulnar carpal bone (arrowheads). **B,** Dorsal 45° lateral-palmaromedial oblique digital radiographic image of the right carpus showing mild enthesophyte and marginal osteophyte formation of the dorsomedial aspect of the radial carpal bone (arrowheads). Note also a bony fragment at the distal aspect of the ulnar carpal bone (arrows). This fragment is likely an incidental finding because IRU was not seen.

and characterized, but I remain skeptical of this lesion as an authentic cause of lameness.^{63,64} Differentiation between genuine avulsion injury and the common radiological abnormalities such as radiolucent defects and fragments that occur commonly at the distal aspect of the ulnar carpal bone is difficult. I have not been able to document IRU on scintigraphic examination of horses with radiological evidence of fracture, radiolucent defects, or radiolucent defects with fragmentation, in this location (Figure 38-17). Fragments removed from this location histologically were consistent with fracture, and the authors differentiated fracture from the common cystic lesions that occur in this location by the presence of actual fragments and the position of the fragments at the palmar transition zone at the confluence of the lateral palmar intercarpal ligament.⁶³ In the clinical report 26 of 37 horses underwent arthroscopic surgery to remove fragments and 20 returned to work, whereas five of nine horses managed conservatively returned to work.⁶⁴ Scintigraphic examination was not performed, and complete clinical examination including diagnostic analgesia was not included for all horses.⁶⁴ Careful

clinical examination and advanced imaging may be necessary to differentiate horses with radiological abnormalities of the distal aspect of the ulnar carpal bone. It is possible that the presence of radiolucent defects, fragments, or a combination of radiological abnormalities in young untrained horses could be associated with the future development of other carpal lameness such as OA and osteochondral fragmentation, but to establish an association would require a large prospective clinical study.

Collateral Ligament

Injury of the dense collateral ligaments of the carpus is rare (see Chapter 67). Usually fracture of the distal aspect of the radius, the carpal bones, or the proximal aspect of the McII and the McIV occurs instead of collateral ligament damage. In foals, collateral ligament laxity is seen commonly and is self-limiting but can contribute to the development of angular limb deformity. Three horses with collateral desmopathy remained lame despite prolonged rest, and ultrasonographic examination was useful to characterize the injury.⁶⁵

Carpal Tenosynovitis and Flexor Tendonitis

See Chapters 69 and 75 for a discussion of carpal tenosynovitis and flexor tendonitis.

Exostoses of the Distal Caudal Aspect of the Radius

An unusual clustering of horses with carpal region pain as a result of carpal tenosynovitis from impingement of small exostoses of the caudal perimeter of the radial physis on structures of the carpal canal has been reported.⁶⁶ I have seen three horses with carpal tenosynovitis as a result of irritation of deep surface of the deep digital flexor tendon by exostoses from the distal, caudal aspect of the radius and acute-onset lameness as a result of hemorrhage and inflammation of the carpal sheath. Signs resolved after tenoscopy and ostectomy. Radiological evidence of small exostoses of the distal, caudal radius is common, and careful clinical examination including diagnostic analgesia should be performed to ensure a correct diagnosis. See Chapters 70 and 75 for more information.

Extensor Tendon

See Chapter 77 for a discussion of extensor tendon injury.

Proximal Suspensory Desmitis

See Chapter 72 for a discussion of proximal suspensory desmitis.

Synovial Ganglion

See Chapter 67 for a discussion of synovial ganglion injury.

Carpal Hygroma

Hygroma refers to a sac, bursa, or cavity filled with fluid. Carpal hygroma usually results from direct and blunt trauma to the dorsal aspect of the joint, including the capsule and overlying extensor tendons and sheaths. Carpal hygroma is an occasional complication after arthroscopic surgery or arthrotomy of the carpus. During arthrotomy, a distinct subcutaneous space over the dorsal aspect of the carpus is encountered, but in most instances

this is a potential rather than a real space. When traumatized, this space fills with fluid, resulting in a large sac. Initially, diffuse edema may be present, and horses may be lame, particularly after flexion, but lameness soon abates. A large, fluid filled, nonpainful swelling results that must be differentiated from extensor tenosynovitis (longitudinal swellings) and herniation of the middle carpal and antebrachiocarpal joint capsules (horizontal swellings). Lameness is usually not observed in horses with chronic hygroma unless a large swelling prohibits carpal flexion. Communication with an extensor sheath or joint capsule is rare, unless previous arthroscopic surgery has been performed and a portal inadvertently was made through a tendon sheath. In naturally occurring carpal hygroma a secretory lining is present, but it must develop from cell differentiation because communication with a source of synovial cells is lacking. Diagnosis is based on clinical signs. Positive contrast radiography and ultrasonographic examination are used to determine extent and communication with nearby structures.

The swelling is usually persistent, but it often does not compromise gait, although swelling does result in a cosmetic blemish. I have heard of resolution after injection with oxytetracycline, atropine, or contrast material. Drainage, with or without corticosteroid injection, and chronic bandaging are usually unsuccessful in permanently resolving swelling. Surgical management in the form of en bloc resection is the treatment of choice for cosmetic results. Simply draining the cavity and inserting through-and-through or closed-suction drains may temporarily resolve

swelling, but recurrence is likely. I attempt resection en bloc without entering the hygroma cavity, but invariably the lining is penetrated. The lining is dissected from all overlying subcutaneous tissues and underlying capsule and tendon sheaths. Once the lining is removed, Penrose drains are placed, a light sterile bandage is applied, and horses recover with a sleeve cast-bandage that is left in place a minimum of 7 to 10 days. Drains are removed in 7 to 10 days when cast material is cut, and then the cast material can be used as a splint over a heavy padded bandage. Horses are given absolute stall confinement for 3 weeks. This treatment is successful but expensive.

Neoplasia

A rare cause of carpal region lameness is neoplasia. Lameness and progressive swelling were seen in a 20-year-old horse with chondrosarcoma of the distal aspect of the radius that caused bony proliferation and swelling of the antebrachiocarpal joint.⁶⁷ I have seen an undifferentiated sarcoma of the distal aspect of the antebrachium causing progressive swelling, mild lameness, and a reduction in carpal flexion in a TB broodmare.

Hypertrophic Osteopathy

Lameness associated with hypertrophic osteopathy (see Chapters 15 and 37) is usually mild, and the condition does not directly affect the carpus, but fibrous and bony swelling of the distal aspect of the radius may cause enlargement of the antebrachiocarpal joint region, prompting radiographic examination.

Chapter 39

The Antebrachium

Lance H. Bassage II and Mike W. Ross

ANATOMY

The antebrachium lies between the elbow and carpus and is composed principally of the radius and small vestigial portion of the ulna and the flexor and extensor muscles. The tendons of the superficial and deep digital flexor muscles, the accessory ligament of the superficial digital flexor tendon, and the carpal sheath are discussed elsewhere (see Chapters 69, 70, and 75). The medial aspect of the antebrachium is relatively devoid of soft tissue coverage, and this is important when considering fractures of the radius. Major neurovascular structures include the median artery (continuation of the brachial artery in the proximal antebrachium), vein, and nerve; the radial, ulnar, and cutaneous antebrachial nerves; and the accessory cephalic and cephalic veins.

CLINICAL DIAGNOSIS AND IMAGING CONSIDERATIONS

Lameness associated with the antebrachial region is relatively unusual. Clinical signs are obvious in horses with unstable radial fractures or in those with marked soft tissue swelling. In others diagnosis can be challenging, and ruling out other causes of forelimb lameness and then using diagnostic imaging to reach a definite diagnosis may be necessary. Perineural analgesia of the median and ulnar nerves (see Chapter 10) is performed to rule out more distal sources of pain.

Definitive diagnosis of most lameness problems of the antebrachium can be made using conventional radiography and ultrasonography, but nuclear scintigraphy is useful for diagnosing incomplete and stress fractures of the radius, enostosis-like lesions, and enthesopathy at the origin of the accessory ligament of the superficial digital flexor tendon.

Osteochondroma of the Distal Aspect of the Radius

See Chapter 75 for a discussion of osteochondroma of the distal aspect of the radius.

Physeal Dysplasia of the Distal Aspect of the Radius (Physitis)

See Chapter 57 for a discussion of physitis.

Traumatic Physisitis and Closure of the Distal Radial Physis

A syndrome of vague forelimb lameness believed to be associated with inflammation or pain originating from the distal radial physis has been recognized in young racehorses in early training. Anecdotally the condition appears to be more prevalent in 2-year-old colts. Distal radial physeal closure determined radiologically occurred earlier in fillies (701 days) than in colts (748 days).¹ Presumably the condition results from repetitive trauma to an open physis. The term *open knees* is commonly used to describe the state of skeletal immaturity. This condition is distinct from physeal dysplasia (physisitis), because the condition is not a developmental abnormality, is not associated with clinically apparent enlargement of the metaphyseal region, and occurs in 2-year-old horses in active training.

Mild to moderate forelimb lameness is vague, without indications of a problem elsewhere in the limb. The condition is usually bilateral, but horses can show unilateral lameness, because one limb is more painful than the other. Horses often have a choppy stride, with the legs carried wide. Focal heat may be present, but swelling is usually absent or minimal, and pain may be difficult to detect. Presumptive diagnosis is made on the basis of history, clinical signs, and ruling out other causes of lameness. A positive response to median and ulnar nerve blocks can be used to confirm that the distal aspect of the antebrachium is the source of pain, but this can also abolish subchondral bone pain in the carpus. Definitive radiological abnormalities are rarely present, but a radiologically open physis supports the diagnosis. Nuclear scintigraphy is generally not helpful, because all horses of this age have moderate-to-intense increased radiopharmaceutical uptake (IRU) at the physis. However, scintigraphy is useful for identifying or ruling out other potential causes of lameness, and asymmetrical radiopharmaceutical uptake (greater in the affected physis of the more severely affected limb) may support the diagnosis.

Treatment consists primarily of rest or a reduction in exercise intensity and systemic nonsteroidal antiinflammatory drugs (NSAIDs). Duration of rest varies with the skeletal maturity of the horse and severity of the condition. Local injection of corticosteroids or other drugs, such as homeopathic remedies, and systemic treatment with anabolic steroids have been used but are of dubious value. For some horses, slow jogging for 4 to 6 weeks may be all that is required; for others, stall confinement with hand-walking exercise progressing to paddock turnout for several months may be necessary. Follow-up radiographs can be used to monitor physeal closure, which is often used to determine the appropriate time to resume harder training.

The issue of distal radial physeal closure, the role of radiographs in making this determination, and how to determine the point when training should commence are controversial. Many trainers and veterinarians customarily obtain radiographs of the distal aspect of the radius of 2-year-olds, and those with open knees (radiological evidence that bony union at the physis is incomplete) are withheld from hard training until the physes have closed. Radiological closure of the distal radial physis generally occurs by 20 to 24 months of age² or slightly later.¹ Scin-

tigraphic activity of the distal radial physis persists well after radiological evidence of closure is observed.³ However, endochondral ossification ceases (biological closure) before fusion is evident radiologically, and in our experience horses with a thin or faintly visible physeal remnant visible radiologically are at low risk for traumatic physisitis.

Because the diagnosis is difficult to substantiate and pain may originate from an undetermined source, giving an accurate prognosis is difficult. If other more common conditions have been ruled out and the diagnosis of traumatic physisitis is accurate, the prognosis is excellent. Many horses remaining in training develop signs of carpal lameness, and traumatic physisitis may simply represent a prodromal phase of early osteoarthritis and bone pain. Finally, no correlation between age or month of closure of the distal radial physes and money won, races won, fastest mile, or fastest win mile during the 2-year-old year was found in Standardbreds.⁴

Radial Fractures

Radial fractures almost always result from external trauma, often a kick from another horse in adults, or from being stepped on or kicked by a mare in foals. Stress fractures of the radius also occur,^{5,6} but in our experience true stress fractures of the radius are rare, and the description of those reported by others is similar to what we have termed *enostosis-like lesions* (see the following discussion). One of us (MWR) recently evaluated images of a 4-year-old Thoroughbred colt in race training, with a history of sudden left forelimb lameness, with a genuine radial stress fracture involving the medial, middiaphyseal cortex (Figure 39-1). Cortical location of stress fractures as determined scintigraphically and radiologically differentiates this injury from enostosis-like lesions.

Clinical signs depend on the severity and location of the fracture. Horses with complete fractures (which are nearly always displaced) are severely lame (non-weight bearing, grade 5) and have marked soft tissue swelling associated with the fracture itself or the site of the original wound. The limb may have an unusual angle, and crepitus is usually audible and palpable. Often an associated wound results from the initial injury or is caused by fragment penetration, especially on the medial aspect of the antebrachium. Horses with incomplete or nondisplaced fractures have moderate to severe lameness (grade 3 to 5) shortly after the injury, but within 12 to 72 hours they are often fully weight bearing and walking with minimal lameness. However, resumption of exercise or turnout often results in the fracture becoming displaced within 1 to 2 days (see Figure 3-4). Horses with true stress fractures have moderate lameness (grade 1 to 3) at a trot.

For horses with complete, displaced (unstable) fractures of the radius the diagnosis is straightforward. Radiology is needed only to define fracture configuration and to determine if repair is possible. Radiographs are *essential* in the initial evaluation of *any* horse with a wound in the antebrachium or over the proximal aspect of the carpus that has a history of acute, moderate-to-severe lameness associated with the injury. Lameness associated with incomplete or hairline fractures of the radius may be transient, but radiographs often reveal obvious or suspicious

Fig. 39-1 • A, Delayed-phase cranial (left image; medial is to the left and proximal is uppermost) and lateral (cranial is left) scintigraphic images of a 4-year-old Thoroughbred colt with acute left forelimb lameness. A focal area (arrows) of increased radiopharmaceutical uptake (IRU) involves the caudomedial cortex of the radius. In the cranial and lateral images, IRU can clearly be seen to involve the cortex rather than the medullary cavity of the radius. Cortical location is diagnostic for a stress fracture rather than an enostosis-like lesion. **B,** Cranial 45° medial-caudolateral oblique digital radiographic image of the left radius showing an oblique stress fracture (arrows) of the caudomedial cortex. (Courtesy Dean Richardson, Kennett Square, Pennsylvania, United States.)

fracture lines (Figure 39-2, A). Any radiological evidence of bone injury, often a localized cortical fragmentation or compression fracture, warrants high suspicion of an incomplete fracture, and a full series of radiographs should be obtained. Any horse that has persistent lameness after antebrachial trauma in which original radiological findings were negative should be reevaluated within 7 to 10 days, when a fracture may be evident. The horse should be confined to box rest in the interim. Diagnosis in horses with incomplete fractures or stress fractures can sometimes be difficult. Scintigraphic examination is important to

Fig. 39-2 • A, Craniocaudal radiographic image of the distal radius of a horse revealing a nondisplaced fracture (arrows). The horse had been found acutely severely lame with a small wound over the distal cranial aspect of the antebrachium earlier that day. **B,** Craniocaudal radiographic image 1 day later. Catastrophic fracture occurred even though the horse was confined to a box stall. The original fracture line (arrows) and the edge of a plastic fence post used as a splint are visible.

differentiate fracture from other problems of the radius, such as enostosis-like lesions.

Emergency management of horses with long-bone fractures has been well described⁷ (see Chapter 86). Horses with unstable fractures should be sedated, wounds should be treated, and a full-limb Robert Jones dressing with splints should be applied. A caudal splint extending from the ground to the point of the elbow (olecranon process) and a lateral splint extending to the withers are attached with tape. The bandage should have a flat surface to allow the lateral splint to be *in contact* with the skin of the upper limb and torso to prevent distal limb abduction. An oversized bandage reduces the effectiveness of the splints. Properly applying external coaptation is time-consuming and difficult, but appropriate stabilization is essential to reduce the risks of further fracture displacement and skin penetration. NSAIDs and broad-spectrum antimicrobial therapy should be administered. Horses should travel facing backward.

Confinement to a stall is *mandatory* for any horse with any radiological abnormality, including focal cortical defects, or with known trauma but with no detectable lesions. Catastrophic failure of the radius often results when small cortical defects or incomplete fractures become displaced (see Figure 39-2, B). We recommend conservative management in adult horses with incomplete or nondisplaced radial fractures. If possible, the horse should be transported to a surgical facility even if conservative management is chosen, because the fracture could become displaced and immediate surgical repair may be necessary. However, transport also involves risks that must be weighed against economic considerations and other factors affecting prognosis. Horses with incomplete fractures should

be strictly confined to a stall for 8 weeks. External coaptation is applied as described previously for 4 to 8 weeks but can be difficult to maintain. Cross-tying is generally unnecessary, because horses tend not to lie down with bulky external coaptation in place. If radiographs reveal acceptable progression of healing after 8 weeks, the horse is restricted to box stall rest with hand-walking exercise for another 2 months. The majority of fractures are clinically healed in 4 months, although complete radiological healing may take up to 6 months or more in adult horses. Paddock turnout is generally allowed after 4 months, and horses return to work 5 to 6 months after injury.

NSAIDs are administered as needed to provide comfort and minimize the potential for contralateral limb laminitis. NSAID administration is usually necessary for only 7 to 10 days, and if pain is not adequately controlled, the horse should be reassessed carefully for fracture displacement or progression or infection associated with any wounds. Antibiotic therapy should be given to horses with wounds or deep pressure sores associated with the bandage and splints.

Horses with complete or displaced radial fractures require open reduction and internal fixation, but the prognosis in adult horses is poor to grave. The current method of choice is the application of two bone plates, one on the cranial surface and one on the lateral or medial surface, depending on fracture configuration.^{8,9} In adult horses, use of the dynamic condylar screw plate can be considered and use of locking compression plates should be encouraged. Repair of fractures located at the most proximal or distal aspect of the radius or those with severe comminution is considerably more difficult, and these horses have a grave prognosis. In foals surgical repair is more successful, and a midshaft transverse or short oblique fracture with minor comminution is most common. Although infection is still a concern, implant or bone failure, seen commonly in adult horses, is less frequent. Physeal fractures result in premature closure of the physis, even if repaired surgically. Plate removal is necessary for foals intended to be used for racing.

Management of horses with rare radial stress fractures consists of rest for 4 months. Horses are given 2 months of box stall rest and 2 months of individual turnout in a small paddock before being returned to training. Follow-up radiographic and scintigraphic examinations are recommended.

Prognosis for horses with incomplete or nondisplaced fractures of the radius is good, but clients should be warned of the possible complications of fracture propagation and contralateral laminitis, if initial lameness is severe. Those that do not develop complications, and in which fractures heal uneventfully, have an excellent prognosis for return to full athletic function. Prognosis for surgical repair of radial fractures in adult horses is poor but depends greatly on fracture configuration and whether the fracture is open. Horses with open fractures have a worse prognosis, because infection is an important and frequent complication. Adult horses with long spiral or oblique fractures are the best surgical candidates, whereas those with comminution or fractures involving the proximal and distal aspects of the radius, in particular those involving the antebrachiocondylar or elbow joints, have a poor-to-grave prognosis. Overall the success rate of surgical management of an adult horse with

a complete radial fracture is no better than 10% and is expensive. If severe comminution exists, the fracture is open, or it involves a joint, euthanasia should be recommended. In foals, prognosis is considerably better, with a good prognosis for survival and a fair-to-good prognosis for future athletic use.^{8,9} Foals with radial fractures involving the distal physis will likely develop angular limb deformity, and prognosis for athletic use is worse than in those with middiaphyseal fractures. The prognosis for horses with rare radial stress fractures is excellent.

Enostosis-like Lesions of the Radius

Enostosis-like lesions are an unusual condition affecting many long bones, including the radius (see Chapters 12 and 19). *Enostosis* is defined as “bone within a bone,” and because the cause has yet to be determined, the term *enostosis-like lesion* is used. Enostosis-like lesions are focal or multifocal intramedullary mild-to-dense radiopacities. Scintigraphically, enostosis-like lesions are associated with mild-to-intense IRU on delayed (bone phase) images (Figure 39-3, A). Lesions may occur in one or more bones simultaneously but are not necessarily associated with lameness.^{10,11} Previously, enostosis-like lesions were described as bone infarcts or bone islands. Histological examination of specimens harvested from an enostosis-like lesion in a humerus revealed changes compatible with ischemia of cancellous bone and bone marrow.¹² Histological changes were similar to those in specimens examined from horses with medullary infarcts or those in bone adjacent to diaphyseal fractures and cortical stress fractures. However, the findings were not pathognomonic or exclusively characteristic of either of these entities.¹² We believe enostosis-like lesions may be caused by primary disruption of medullary vasculature and secondary development of bone sclerosis. Enostosis-like lesions are possibly an atypical form of bone infarct. Enostosis-like lesions are frequently found close to a nutrient foramen.¹⁰ Because enostosis-like lesions occur in adult horses of all ages and performance categories, they are not likely to be stress fractures.

Although enostosis-like lesions can be an incidental radiological or scintigraphic finding of the radius, or most long bones, lameness apparently attributable to the condition occurs in approximately 50% of affected horses. Lameness from enostosis-like lesions is most common in horses with lesions involving the humerus and femur, whereas in other bones such as the radius and tibia, signs of lameness may be subtle or nonexistent.¹³ An unusual clustering of Thoroughbred racehorses has been documented, with acute, forelimb or hindlimb lameness referable to enostosis-like lesions of the radii and tibiae, respectively, mimicking lameness seen in racehorses with stress fractures of these bones.¹³ In horses with clinically relevant enostosis-like lesions, lameness is usually mild but may be severe. Although enostosis-like lesions can affect many bones simultaneously, lameness is usually restricted to a single limb.

Because completely abolishing pain originating from the radius may be difficult using diagnostic analgesia, in most horses with enostosis-like lesions diagnosis is made by ruling out other potential causes of lameness. Enostosis-like lesions must be differentiated from true stress fractures. It is imperative that two perpendicular scintigraphic images be obtained, to allow differentiation of cortical and medullary IRU (see Figure 39-1). Although treatment of

Fig. 39-3 • A, Lateral delayed (bone) phase scintigraphic image showing focal, intense increased radiopharmaceutical uptake (*arrow*) in the medullary cavity consistent with an enostosis-like lesion. Two scintigraphic images were compared, and increased radiopharmaceutical uptake was determined to involve the medullary cavity rather than the cortex. **B,** Lateromedial radiographic image reveals intramedullary increased radiopacity (*arrow*) on the endosteal surface and adjacent to the nutrient foramen, radiological signs typical in horses with enostosis-like lesions.

horses with enostosis-like lesions and of those with stress fractures is similar, cause and recurrence are different. Enostosis-like lesions are associated with mild-to-intense IRU in the medulla. In our experience enostosis-like lesions causing lameness are usually moderately to intensely active. Radiographs reveal corresponding single or multiple, focal or multifocal areas of increased radiopacity within the medullary cavity (see [Figure 39-3, B](#)). The lesions are frequently in contact with the endosteal surface and are most often in close proximity to the nutrient foramen. In the radius, follow-up scintigraphic and radiological evaluation 4 to 9 months after initial diagnosis often reveals resolution of the enostosis-like lesions, although resolution of radiological changes lags behind those visible scintigraphically.

Treatment of horses with enostosis-like lesions thought to be causing lameness is nearly identical to that for those with stress fractures. NSAIDs (phenylbutazone, 2.2 mg/kg, bid) are administered for 5 to 10 days or longer depending on degree of lameness. Horses are restricted to stall rest with hand-walking exercise for 2 months, followed by a minimum of 2 months in an individual small paddock. Follow-up clinical, scintigraphic, and radiographic evaluation is recommended. Prognosis for most horses with enostosis-like lesions is excellent, and recurrent lameness is rare, although occasionally longer convalescence (6 to 9 months) is required.

Osseous Cystlike Lesions of the Distal Radius

Osseous cystlike lesions occur in immature¹⁴ and adult horses¹⁵ and may result from osteochondrosis or trauma.

Occasionally, osseous cystlike lesions occur secondary to severe osteoarthritis of the antebrachicarpal joint. Lameness ranges from mild to severe (grade 1 to 4) and may be sudden or insidious in onset.^{14,15} Often no localizing clinical signs are present, unless osseous cystlike lesions are secondary to osteoarthritis of the antebrachicarpal joint, when effusion may be present.

Lameness is localized to the antebrachicarpal joint and distal aspect of the radius by intraarticular analgesia or by using median and ulnar nerve blocks. Response to intraarticular analgesia of the antebrachicarpal joint is inconsistent; most horses show partial improvement. Scintigraphy is useful in horses in which diagnostic analgesia fails to localize lameness. Radiographs reveal a well-defined radiolucent defect in the subchondral bone, often with a sclerotic margin ([Figure 39-4](#)), with or without communication with the antebrachicarpal joint.

Management remains controversial, and a universally accepted method is not currently available. Successful surgical management using an extraarticular approach, debridement, and cancellous bone grafting has been described.¹⁵ Osseous cystlike lesions that enter the antebrachicarpal joint can be debrided using an intraarticular approach, whereas those without communication are best managed using an extraarticular approach. Nonsurgical management has been successful and consisted of restricted exercise, with or without intraarticular administration of hyaluronan.¹⁴ We treat horses conservatively. Duration of restricted exercise and number and type of intraarticular injections are determined on a case-by-case basis. Horses are given a minimum of 4 to 6 months of rest, or longer if

Fig. 39-4 • A, Craniocaudal digital radiographic image of the distal aspect of the right radius of a Standardbred weanling with an osseous cystlike lesion (*arrows*) of the distal, medial aspect of the radius, close to the antebrachio-carpal joint. This weanling was given stall rest for 4 months, and three intraarticular injections with hyaluronan and methylprednisolone acetate were performed. **B,** Seven-month follow-up craniocaudal image showing near complete resolution of the bone cyst.

gradual improvement in clinical signs is seen. Conservative management is the first choice in immature horses (<2 years of age). Extraarticular corticosteroid injection using a small drill bit has been successful in other sites and may be applicable for lesions involving the distal aspect of the radius. If little improvement is seen after 6 months, then surgical debridement (with or without grafting) should be considered. Limited data are available on which to base prognosis, which may be better in immature horses (<2 years of age).

Desmitis of the Accessory Ligament of the Superficial Digital Flexor Tendon

See Chapter 75 for a discussion of desmitis of the accessory ligament of the superficial digital flexor tendon.

Acute Caudal Antebrachial Myositis

Myositis and traumatic injury of the muscles in the caudal aspect of the antebrachium are relatively rare. Horses that compete over jumps at speed such as Three Day Event, timber, and steeplechase horses appear to be at risk to traumatize these muscles, presumably as a result of hyperextension of the metacarpophalangeal and carpal joints during landing. Occasionally, horses develop inexplicable myositis or injury of these muscle unassociated with a known traumatic event. Infectious myositis can result from puncture or kick wounds (see the following discussion).

Presumptive diagnosis can usually be made on the basis of history and clinical signs. The antebrachium should be carefully evaluated for even small puncture wounds. A recent but seemingly unrelated area of injury or small wound in the elbow or axillary region may be an important part of the history or physical examination. The clinician

should measure rectal temperature. Pyrexia indicates infection. Radiography should be performed to rule out bony injury, such as an incomplete fracture of the radius. Ultrasonographic examination reveals heterogeneous echogenicity within the bellies and between the fascia of the affected muscles, compatible with fiber disruption and hematoma formation.

Treatment consists of systemic NSAID administration (7 to 10 days) and hydrotherapy. Cold water hosing is administered for 15 to 20 minutes twice a day for 5 days, and then warm water hosing is initiated for 5 days. Broad-spectrum antimicrobial therapy is given if infection is suspected (see the following discussion). Horses are confined to a stall for 6 weeks, and hand-walking exercise is initiated, beginning at 5 minutes twice a day and increasing by 5 minutes each week. Passive flexion and extension of the carpus (30 to 50 repetitions daily) helps to improve range of motion and possibly fiber alignment. Clinical and ultrasonographic evaluation is recommended after 6 weeks. Work should not commence until carpal flexion is normal and the horse is sound. The prognosis for return to full athletic function is good.

Infectious Myositis and Cellulitis

Small puncture wounds in the antebrachium, elbow, and pectoral region can result in infections that cause tremendous antebrachial swelling associated with subcutaneous or deeper tissues. Small wounds may seal over quickly but result in inoculation of bacteria into deeper tissues, causing diffuse cellulitis or infectious myositis. Abrasions from equipment such as hobbles in a Standardbred racehorse can lead to deep infections of the proximal aspect of the antebrachium. Usually swelling is also present in the distal aspect of the limb, and the carpal sheath may show

sympathetic effusion. Infectious myositis may lead to deep abscess formation. Lameness is usually moderate to severe. The horse may be depressed and is usually pyrexia. White blood cell count and fibrinogen concentration are raised. Skin sloughing may develop with aggressive infections caused by *Streptococcus* or *Staphylococcus* species. Radiographs should be obtained, because a radial or ulnar fracture may occur concurrent with infection, but radiological findings are usually negative unless osteitis of the radius or ulna exists (see the following discussion).

Treatment involves administration of broad-spectrum antimicrobial drugs and NSAIDs and the application of topical warm water hydrotherapy. Full-limb bandaging is recommended to reduce swelling in the antebrachium and distal aspect of the limb. Horses with diffuse cellulitis usually respond quickly (within 3 to 5 days), whereas those with deeper infections require prolonged therapy. Horses with an abscess need surgical drainage.

Osteitis and Osteomyelitis of the Radius and Ulna

Osteitis and osteomyelitis of the radius and/or ulna can result from penetrating trauma, most commonly a kick. Clinical signs are similar to those seen with extensive soft tissue infection (see the preceding discussion), and some component of infectious myositis or cellulitis is present in most horses with osteomyelitis and in many with osteitis. Radiographs are diagnostic (Figure 39-5). Focal cortical trauma or fractures may also be present (see preceding section on radial fractures). Radiographs are indicated in all horses with infectious antebrachial myositis or cellulitis that exhibit a poor response to appropriate antimicrobial treatment and other ancillary therapy. Osteitis and osteomyelitis should be suspected in all horses with radial or ulnar fractures or focal cortical trauma associated with an open wound that subsequently develop signs of soft tissue infection. Infectious arthritis of the elbow or carpus may be present, either from direct involvement with a wound, or extension of the bone infection into the joint.¹⁶

Treatment is similar to that outlined for infectious myositis or cellulitis. Additional therapeutic options include surgical debridement and local antimicrobial delivery, such as intraosseous antimicrobial perfusion and use of antimicrobial-impregnated bone cement. The reader is referred to Chapter 65 for details on the diagnosis and management of infectious arthritis. Prognosis for horses with localized osteitis is generally favorable. Prognosis for those with osteomyelitis is more guarded and is dependent on the extent and severity of the infection, as well as the nature of any concurrent problems or injuries.

Swelling of the Antebrachium Associated with Other Conditions

Horses with infectious arthritis of the elbow joint, fractures of the proximal aspect of the radius or ulna, or distal

Fig. 39-5 • Lateromedial radiographic image of the right radius of a horse with extensive osteomyelitis resulting from a penetrating wound. Note the characteristic periosteal proliferative reaction (white arrows) and the osteolytic and osteoproliferative changes within the medullary cavity (black arrows).

humeral fractures often have swelling of the antebrachium. These conditions should be kept in mind if diagnosis of a primary problem in the antebrachium cannot be made.

Hypertrophic Osteopathy

Hypertrophic osteopathy is an unusual disorder involving bilaterally symmetrical proliferation of fibrous tissue and periosteal bone in the appendicular and, less frequently, the axial skeleton, involving the metaphyseal and diaphyseal regions of several bones of all limbs.^{17,18} Hypertrophic osteopathy may be associated with disease in the thorax or abdomen or with vascular abnormalities. Cause is unknown but may be neurogenic, mediated by the vagus nerve, or hormonal, leading to changes in regional blood flow. Clinical signs include soft tissue swelling and stiffness or lameness, often associated with elevated fibrinogen levels. Radiology of affected bones reveals palisading periosteal new bone. Identification of the primary lesion is important, because bony lesions may resolve with successful treatment of the underlying disease.¹⁷⁻²⁰ NSAIDs may ameliorate clinical signs.

Chapter 40

The Elbow, Brachium, and Shoulder

Sue J. Dyson

ANATOMICAL CONSIDERATIONS

The elbow joint consists of the humerus, radius, and ulna. The distal aspect of the humerus develops from three ossification centers: the diaphysis, the distal epiphysis, and the epiphysis of the medial condyle. These close radiologically at 11 to 24 months of age. The radius and ulna have a single proximal epiphysis. The radial physis closes radiologically at 11 to 24 months of age, but the ulnar physis does not close until 24 to 36 months of age. Physeal closure occurs later in non-Thoroughbred (TB) breeds.

The cranial aspect of the olecranon of the ulna has articular and nonarticular components. The anconeal process and trochlear notch articulate with the humerus. At the distal part of the trochlear notch is a distinct ridge. Distal to this is a large, non-weight-bearing synovial fossa.

The elbow is a ginglymus joint, supported medially and laterally by collateral ligaments. The medial collateral ligament consists of a long superficial part and a deeper short part. The medial collateral ligament arises from an eminence on the medial epicondyle of the humerus. The deep part inserts on the radial tuberosity; the superficial part inserts on a more distal prominence, just distal to the interosseous space between the radius and ulna. The lateral collateral ligament arises from a depression in the lateral epicondyle of the humerus and inserts on the lateral tuberosity of the radius, just distal to the joint margin. The joint capsule is extremely thin caudally, where it forms a pouch in the olecranon fossa. Cranially the joint capsule is strengthened by oblique fibers and blends with the collateral ligaments medially and laterally.

The most readily palpable landmarks are the olecranon of the ulna and the lateral collateral ligament of the humero-radial joint. Minimal soft tissue covers the lateral aspect of the elbow, making it vulnerable to the effects of direct trauma and penetrating wounds.

The humerus is surrounded by muscles, which largely protect it from the effects of direct trauma. The deltoid tuberosity on the cranio-lateral aspect is usually readily palpable and is potentially vulnerable to the effects of direct trauma. The deltoid tuberosity is the most useful landmark for identifying the point for needle insertion for synoviocentesis of the intertubercular (bicipital) bursa. The proximal aspect of the humerus has several centers of ossification for the humeral head and the greater and lesser tubercles, which gradually fuse at 3 to 5 months of age. Radiological closure of the proximal humeral physis occurs at 24 to 36 months of age.

The scapula has four centers of ossification: the scapular cartilage, body of the scapula, cranial part of the glenoid

cavity of the scapula, and supraglenoid tubercle and coracoid process. The ossification center for the cranial part of the glenoid cavity fuses directly with the body of the scapula, and this is complete radiologically by 5 months of age. The physis between the supraglenoid tubercle and coracoid process and the body of the scapula closes radiologically at 12 to 24 months of age—earlier in TB and TB crossbreeds than in ponies. These physeal lines remain weak links, and it is through these that fractures of the supraglenoid tubercle and cranial part of the glenoid cavity of the scapula tend to occur.

The scapula is attached by the serratus ventralis muscles to the axial skeleton. Other muscles involved in attachment of the thoracic limb to the trunk and neck are the four pectoral muscles, the brachiocephalicus, and omotransversarius.

The brachial plexus lies on the axial aspect of the scapula and is derived from the sixth, seventh, and eighth cervical nerve roots and the first thoracic nerve. These nerve roots are potentially vulnerable to trauma where they exit the cervical and cranial thoracic vertebrae, and these are relatively common sites for neuroma formation after trauma. The nerves of the brachial plexus are responsible for innervation of many of the principal muscles of the shoulder region.

The scapulohumeral or shoulder joint is unusual because of the absence of collateral ligaments. Stability therefore depends on muscular support on the medial and lateral aspects by the subscapularis, teres minor, infraspinatus, and supraspinatus. Cranial support is provided by the biceps brachii and supraspinatus, and caudal support is rendered by the long head of the triceps brachii. Overlying muscles make it impossible in mature horses to appreciate distention of the joint capsule by palpation. The joint capsule attaches closely to the margins of the scapulohumeral joint, and this, together with the surrounding muscles, restricts arthroscopic evaluation within the joint. The suprascapular nerve wraps around the cranial margin of the scapula proximal to the supraglenoid tubercle and provides innervation to the infraspinatus and supraspinatus muscles.

Considering its embryological development and function, the so-called *intertubercular (bicipital) bursa* would be more appropriately called a *tendon sheath*.¹ The bursa surrounds the tendon of biceps brachii, which originates from the supraglenoid tubercle of the scapula. The craniodistal pull of the biceps brachii results in cranial and distal displacement of fractures of the supraglenoid tubercle. Communication was identified between the scapulohumeral joint capsule and the intertubercular bursa using contrast arthrography in 3 of 18 limbs (17%)²; thus in some horses intraarticular analgesia of the scapulohumeral joint has the potential to cause improvement in lameness caused by pain arising from the intertubercular bursa. The tendon of biceps brachii is partially cartilaginous proximally and passes over the smooth intertubercular groove of the humerus and then becomes predominantly muscular with a tendinous core.

The most important palpable landmarks in the shoulder region are the cranial and caudal eminences of the greater tubercle of the humerus. The notch between these

eminences provides the portal for arthrocentesis of the scapulohumeral joint. The scapular spine is usually readily palpable except in exceptionally fat horses or heavily muscled individuals and becomes more prominent if the supraspinatus or infraspinatus muscles atrophy.

DIAGNOSIS

Clinical Signs

In the adult horse lameness associated with the elbow or shoulder region is comparatively rare, except after direct trauma caused by a fall, collision with a solid object such as a gatepost, or collision with another horse. In immature athletic horses, stress fractures of the scapula, humerus, and radius; osseous cystlike lesions; and osteochondrosis are quite common.

Lameness associated with the shoulder or elbow region is usually sudden in onset and generally moderate to severe. After trauma to the shoulder or elbow, or in association with severe lameness, the horse tends to stand with its weight inclined toward the contralateral limb, not fully load bearing on the lame limb. The horse may resent turning on the limb. Muscle atrophy in the shoulder region is not specific for lameness associated with the proximal aspect of the limb but is often more severe than if the pain arises farther distally. Rapid loss of the bulk of supraspinatus and infraspinatus muscles alone is likely to reflect damage to the suprascapular nerve, whereas involvement of additional muscles is more likely to reflect a brachial plexus injury. Swelling in the elbow or shoulder region usually reflects direct trauma but may be seen with subluxation or luxation of the shoulder or elbow joint. Patchy sweating is sometimes seen with a lesion of the brachial plexus. Pain elicited by deep palpation is relatively unusual and is generally associated with direct trauma. Care should always be taken to compare the reaction with that to palpation of the contralateral limb. The reaction to manipulation of the proximal limb joints should also be interpreted with care because many normal horses resent extreme flexion, extension, or abduction.

Many normal horses show some resentment of firm palpation of the brachiocephalic muscles at the base of the neck. These muscles often become sore with a more distal source of pain causing lameness. Primary muscle pain causing lameness does sometimes occur and is associated with a more marked pain reaction on palpation and muscle spasm. It may cause a lameness most evident when the horse is ridden at the walk, characterized by lifting of the head and neck as the ipsilateral limb is protracted. Lesions of the tendon of biceps brachii are also sometimes associated with lameness that is worse at walk than trot.

If lameness is mild, then the character of the lameness is nonspecific; but if lameness is moderate to severe, it is often characterized by a shortened cranial phase of the stride, a reduced height of the arc of foot flight, and a marked head lift and nod. These gait characteristics are evident at the walk and the trot. Observation of the moving horse from the front and the side is particularly useful. The horse may pivot on the lame limb when turning. The gait characteristics of shoulder slip (see page 473) are more easily identified by observing the horse walking toward you. Lameness is frequently accentuated with the lame limb on the outside of a circle. In horses with proximal

limb lameness, especially associated with muscle fibrosis, lameness may be evident only when the horse is ridden, performing specific movements. Manipulative tests of the proximal limb joints are rather nonspecific and frequently unrewarding.

Lameness may fluctuate in degree under different circumstances and within an examination period; therefore it is important to observe the horse for a sufficient length of time before proceeding with local analgesic techniques. If lameness is apparent only when the horse is ridden, the horse may be sensitive to the diagonal on which the rider sits.

Lameness caused by trauma resulting in only bruising usually improves rapidly, within a few days. Persistence of lameness merits further investigation.

Local Analgesia

It is important to recognize the potential effect of a median nerve block, performed in the proximal antebrachium, on elbow pain. Elbow lameness may be substantially improved, presumably because of local diffusion of the local anesthetic solution. Techniques for intraarticular analgesia of the elbow and shoulder and intrathecal analgesia of the intertubercular bursa are described in detail in Chapter 10. Intraarticular analgesia of the elbow and shoulder joints usually improves but rarely eliminates pain associated with either joint. The elbow and shoulder joints are relatively large; therefore use of at least 10 mL of local anesthetic solution (mepivacaine, 2%) is recommended for the elbow joint and 20 mL for the shoulder joint. Retrieving synovial fluid from each joint is usually possible. Absence of resistance to injection is not a guarantee that the needle is in an intraarticular location. Walking the horse after the block facilitates circulation of the local anesthetic solution throughout the joint. Although improvement in lameness may be seen rapidly, within 10 to 15 minutes after injection, at least 1 hour should elapse after the block before the result is considered negative. The block generally is effective for up to 2 hours. The block usually has no influence over pain associated with periarthicular structures.

When performing intraarticular analgesia of the shoulder, it is important to recognize that there is communication with the intertubercular bursa in some horses. In some horses instability of shoulder, so-called *shoulder slip*, appears transiently (for up to 2 hours) after injection of local anesthetic solution. This prohibits interpretation of the nerve block. The cause is presumably diffusion of local anesthetic solution to nerves innervating the muscles responsible for maintaining stability of the shoulder. Positive-contrast arthrography has shown that injection of volumes greater than 20 mL pose a danger of pooling at the site of injection or leakage from the joint capsule. An experimental study demonstrated that deposition of mepivacaine over the suprascapular nerve could result in transient shoulder slip, but this may be the result of diffusion to affect the brachial plexus (see page 473).³

Intrathecal analgesia of the intertubercular bursa may improve lameness associated with lesions of the tendon of biceps brachii, the bursa itself, or the humeral tubercles, but accurate intrathecal injection may not be reliable.⁴ The bursa is large, and use of 20 mL of local anesthetic solution is recommended.

False-negative results to both intraarticular analgesia of the shoulder and elbow joints and intrathecal analgesia of the intertubercular bursa may occur, and radiological, scintigraphic, and ultrasonographic evaluation of these areas is indicated if clinical signs are suggestive of shoulder or elbow region pain. Many other potential sources of pain in the proximal limb cannot be desensitized by local anesthetic techniques. If the response to distal limb analgesia and the blocks described previously is negative, nuclear scintigraphic evaluation may be warranted.

Assessment of Muscles

Electrical stimulation of muscles may help to identify muscle-related pain (see page 824).

IMAGING

Radiography and Radiology

Radiographic examination of the elbow requires a minimum of mediolateral and craniocaudal images.⁵ The limb should be pulled forward sufficiently to avoid the pectoral muscle mass to evaluate the distal aspect of the humerus properly. Additional oblique images may be of value in selected horses. Routine radiographic examination of the scapulohumeral joint should include mediolateral and craniomedial-caudolateral oblique images. In some horses cranioproximal-craniodistal oblique images of the humeral tubercles are useful. Examination of the entire length of the humerus can be difficult, because often when such examination is indicated, the horse has pain and is reluctant to allow the limb to be adequately protracted. Accurate evaluation of the entire scapula is also not easy because of superimposition over the thoracic vertebrae and the contralateral limb.

Fast-speed, rare earth screens and appropriate film are essential if using conventional radiography. Use of a grid will greatly enhance image quality, especially in the shoulder region. High exposure factors are required (e.g., 100 kV, 100 mAs, for a mediolateral image of the shoulder). Underexposure will result in lesions being missed.

It is important to recognize that the cranial articular margin of the proximal radius has several lips that should not be confused with osteophytes (Figure 40-1). The cranial

Fig. 40-1 • Mediolateral radiographic image of the elbow joint of a normal adult horse. The lips on the cranioproximal aspect of the radius are a normal radiological feature.

tuberosity of the proximal aspect of the radius may appear roughened in slightly oblique mediolateral views.

In the scapulohumeral joint a small circular radiolucent region is sometimes seen in the subchondral bone in the middle of the glenoid cavity of the scapula (Figure 40-2). A radiolucent edge effect is often seen in the proximal humerus, the result of superimposition of the lateral rim of the glenoid cavity of the scapula.

Ultrasonography

Diagnostic ultrasonography is invaluable for assessing muscle structure in the shoulder region. Normal muscle has a homogeneous echogenicity. Identification of hyper-echogenic regions indicative of muscle necrosis, fibrosis, or mineralization is usually associated with lameness.

Evaluation of the elbow joint itself is limited in the weight-bearing position because of the difficulty in getting access medially. Examination of the lateral collateral ligament of the humeroradial joint is straightforward. For evaluation of the medial aspect, the limb should be pulled forward, but unless the medial collateral ligament is under tension, its echogenicity may lack homogeneity.

In the shoulder region ultrasonography is important for assessing the intertubercular bursa, humeral tubercles, tendon of biceps brachii (Figure 40-3, A and B), tendons of insertion of the supraspinatus and infraspinatus muscles (Figure 40-3, C and D), and the infraspinatus bursa (Figure 40-3, B).⁶⁻¹⁰ Care should be taken to ensure that the horse is fully load bearing on the limb, because hypoechogenic artifacts can be created, especially in the tendon of biceps brachii, unless the musculature is under tension. The medial and lateral lobes of the tendon of biceps brachii and the isthmus between them should each be evaluated individually, because getting the entire structure into focus simultaneously is difficult.

Nuclear Scintigraphy

Nuclear scintigraphic evaluation of the proximal aspect of the forelimbs is indicated if the responses are negative to median and ulnar nerve blocks, intraarticular analgesia of

Fig. 40-2 • Mediolateral radiographic image of a scapulohumeral joint of a normal adult horse. There is a small lucent zone in the subchondral bone in the middle of the glenoid cavity of the scapula (arrow). Note also the radiolucent band crossing the humeral head and the edge effect caused by superimposition of the articular margins of the scapula.

Fig. 40-3 • **A**, Transverse ultrasonographic image of the cranial proximal aspect of the humerus of a normal horse. Medial is left. There is a small amount of anechogenic fluid within the intertubercular bursa, and the contour of the humeral tubercle is smooth (*arrow*). **B**, Longitudinal ultrasonographic image of the tendon of biceps brachii and the overlying brachiocephalicus muscle. Proximal is left. **C**, Transverse image of the tendon of infraspinatus within the infraspinatus muscle. **D**, Transverse ultrasonographic image of the insertion of the infraspinatus on the proximal aspect of the humerus. The anechogenic space, the infraspinatus bursa, appears between the tendon of insertion and the bone. *BB*, Medial lobe of the tendon of biceps brachii; *BR*, brachiocephalicus; *OM*, omotransversarius; *SS*, medial tendon of insertion of the supraspinatus.

the elbow and shoulder joints, and intrathecal analgesia of the intertubercular bursa. Scintigraphy is also indicated if history and clinical signs suggest a stress fracture. Scintigraphy has also been useful for identifying enostosis-like lesions (bone islands) in the humerus and fractures of the deltoid tuberosity of the humerus. Care should be taken to localize any region of increased radiopharmaceutical uptake (IRU) as precisely as possible to identify the likely underlying pathological condition. IRU in the first rib can easily be misinterpreted unless a cranial image is obtained to separate the scapula and humerus from the underlying rib. Examination of the scintigraphic images should include careful assessment of the soft tissues, because abnormal uptake of the radiopharmaceutical in muscle can sometimes be identified in bone phase images.

DIFFERENTIAL DIAGNOSIS

Elbow

Osteoarthritis

Osteoarthritis (OA) of the elbow is relatively unusual and tends to be seen in older athletic horses. Often the horse has a history of trauma. The horse may resent manipulation of the elbow, but appreciating joint effusion is usually not possible. Lameness often varies in degree, within and between examinations, and is usually worst on a hard surface, especially on a circle.

Intraarticular analgesia improves lameness. Periarticular osteophyte formation, alterations in subchondral bone opacity, and narrowing of joint space width may be seen radiologically (Figure 40-4). Care should be taken not to misinterpret as osteophytes normal bony lips on the dorsoproximal aspect of the radius in a mediolateral image.

The repeated use of intraarticular polysulfated glycosaminoglycans has been most effective in resolving lameness, but the long-term prognosis for return to full athletic function is guarded.

Osseous Cystlike Lesions

Osseous cystlike lesions occur most commonly medially in the proximal radial epiphysis (Figure 40-5) and usually result in acute-onset, relatively severe lameness in immature athletic horses.

Lameness may vary greatly in degree, within and between examinations, and is usually substantially improved by intraarticular analgesia. In addition to a well-defined osseous cystlike lesion, there is often periosteal new bone on the proximal medial metaphyseal region of the radius. Intraarticular medication with hyaluronan or corticosteroids (triamcinolone acetonide or methylprednisolone acetate) has resulted in successful resolution of lameness.^{1,11} In some horses the osseous cystlike lesions have resolved radiologically. Surgical treatment by curettage of the cyst using an extraarticular approach has been successful in some horses, but fracture through the cyst has been a recognized complication.¹² Recurrent lameness after surgical treatment is also possible.¹³ An ill-defined osseous cystlike lesion is occasionally seen in older horses with OA of the elbow with no known previous history of lameness; it is likely that the cystlike lesion had been present

Fig. 40-4 • Mediolateral (A) and craniocaudal (B) (medial is to the left) radiographic images of the elbow joint of a 9-year-old event horse with left forelimb lameness alleviated by intraarticular analgesia of the elbow. The periarticular osteophytes (arrows) and subtle narrowing of the joint space medially indicate osteoarthritis. The horse failed to respond to intraarticular medication.

asymptotically before the development of pain associated with OA.

Less commonly, large, less well-defined osseous cystlike lesions have been identified in the distal aspect of the humerus in young Thoroughbreds being prepared for the yearling sales or just after entering training.¹ Lameness is acute in onset, persists despite box rest, and is generally not influenced by intraarticular analgesia of the elbow. Nuclear scintigraphic examination reveals a region of IRU in the distal aspect of the humerus, more centrally located than that associated with a stress fracture (see page 463). Careful radiological examination reveals a less well-defined osseous cystlike lesion. Conservative management has resulted in persistent lameness, and the results of surgical treatment have been disappointing. Young horses with smaller osseous cystlike lesions in the distal medial humerus have been identified and have responded to conservative management.¹²

Fig. 40-5 • Craniocaudal radiographic image of the proximal aspect of the radius of a 3-year-old Thoroughbred racehorse with left forelimb lameness, which substantially improved with intraarticular analgesia of the elbow. There is a well-defined osseous cystlike lesion in the proximomedial aspect of the radius. Note also the periosteal new bone on the proximomedial aspect of the radius. Intraarticular medication with hyaluronan resolved lameness, and the horse raced successfully.

Osteochondrosis

The elbow is a relatively rare location for osteochondrosis, but occasionally lameness is identified in young TBs and STBs in training associated with osteochondrosis lesions of the distal aspect of the humerus or the proximal aspect of the radius. Lameness is improved by intraarticular analgesia. Various radiological changes have been identified. Results of medical and surgical management have been disappointing. Osteochondrosis lesions of the anconeal process of the ulna also occur rarely,¹⁴ but they should not be confused with a separate ossification center in young foals.¹⁵

Stress Reactions in Subchondral Bone

Intermittent lameness has been identified in a small number of event horses associated with an assumed stress reaction in the subchondral bone of the distal aspect of the humerus.¹ Lameness is induced by jumping but tends to resolve if the horse is not jumped. Lameness may be improved by intraarticular analgesia of the elbow (curious). No bony abnormalities have been identified radiologically. Nuclear scintigraphic examination reveals a region of IRU in the subchondral bone of the distal aspect of the humerus. Treatment with box rest and controlled walking exercise for 3 months has resulted in resolution of lameness and a normal distribution of the radiopharmaceutical. Horses have been able to return to full athletic function without recurrent injury.

Collateral Ligament Injury

Injury to the collateral ligaments of the elbow is not common and usually results from a traumatic injury such as a fall. Damage to the lateral collateral ligament has been

Fig. 40-6 • Craniocaudal radiographic image of the elbow of 15-year-old pony that had chronic left forelimb lameness after a fall. There is entheses new bone at the attachments of the lateral collateral ligament of the humeroradial joint (*white arrows*) with mineralization within the ligament. There is also new bone on the proximomedial aspect of the radius (*black arrows*). Periarticular osteophyte formation was also visible in a mediolateral image. Ultrasonographic examination revealed poor fiber pattern within the lateral collateral ligament. Postmortem examination confirmed desmitis of the lateral collateral ligament and osteoarthritis of the elbow joint.

identified most frequently. Severe injuries may also be associated with injury to the joint capsule, and osteoarthritis may ensue. Lameness is acute in onset. Subtle soft tissue swelling may be appreciated in the elbow region, and manipulation of the elbow may induce pain. Lameness may be partially improved by intraarticular analgesia of the elbow. If damage is restricted to extraarticular structures, then the response may be negative. Nuclear scintigraphic examination may be helpful in these horses. IRU occurs at the sites of ligament attachment on the distal aspect of the humerus and proximal aspect of the radius.

Definitive diagnosis requires ultrasonographic examination and identification of disruption of the normally linear pattern of echoes within the ligament. Sometimes periosteal new bone or avulsion fractures can be identified at the region of ligamentous attachment.¹⁶ Radiographic examination should also be performed to identify any concurrent pathological condition of the bone, such as enthesophyte formation, an avulsion fracture, or secondary OA (Figure 40-6).

Horses with minor lesions have responded well to a period of box rest and controlled walking exercise, but those with lesions that have been associated with entheses new bone formation often have had persistent lameness and have developed OA.

Luxation

Luxation of the elbow joint is usually seen with a fracture of the olecranon or proximal aspect of the radius or separation of the radius and ulna, although luxation occasionally

occurs alone. Lameness is acute in onset and severe and is associated with considerable swelling in the elbow region. Comprehensive radiographic examination is essential to determine if one or more concurrent fractures are present. Surgical repair can be considered, but the prognosis for athletic function is poor.

Enthesopathy of the Biceps Brachii

Tearing of the attachment of the biceps brachii from the cranioproximal aspect of the radius may be associated with a traumatic injury such as a fall, but frequently history does not suggest the cause. Lameness is sudden in onset and often not associated with any localizing signs, except pain on manipulation of the elbow in horses with acute lameness. The lameness has no particular characteristics. The response to local analgesic techniques is negative. Radiographic examination may reveal periosteal new bone on the cranioproximal aspect of the humerus in horses with chronic lameness¹⁷ (Figure 40-7). Sometimes an adjacent mineralized fragment is present, an avulsion fracture or dystrophic mineralization. Some new bone formation on the cranioproximal aspect of the radius can be seen in normal horses, reflecting previous injury; therefore care should be taken in interpreting its current significance. Nuclear scintigraphic examination is helpful for acute lameness before periosteal new bone develops and in horses with chronic lameness. Ultrasonographic evaluation has not been helpful. Treatment is by rest. The prognosis is guarded to fair.

Avulsion of the Origin of the Ulnaris Lateralis

The ulnaris lateralis functions to flex the carpus and extend the elbow. An avulsion fracture at the origin of the ulnaris lateralis, from a site caudal and distal to the origin of the lateral collateral ligament of the humeroradial joint, is a rare cause of lameness. Lameness is acute in onset and moderate to severe, following a fall, resulting in diffuse soft tissue swelling on the lateral aspect of the elbow. Diagnosis is based on radiography and ultrasonography. A nonarticular avulsion fragment and enlargement and marked disruption of the tendon of origin of the ulnaris lateralis are present.¹⁸

Fig. 40-7 • Mediolateral radiographic image of the right elbow of 9-year-old show jumper with chronic right forelimb lameness that no local analgesic technique influenced. There is new bone on the cranial tuberosity of the radius at the site of insertion of the biceps brachii (arrow). Nuclear scintigraphy gave evidence of increased bone modeling at this site. The horse had persistent lameness despite prolonged rest.

Fracture of the Olecranon

Fracture of the olecranon of the ulna usually results from a kick or fall, resulting in acute-onset, severe lameness. The horse may stand with the elbow dropped because of lack of an effective attachment of the triceps, the principal extensor of the elbow. Soft tissue swelling may or may not be palpable. Traction on the summit of the olecranon elicits pain. Although many fractures are comminuted, detecting crepitus is unusual. Radiographic examination should include mediolateral and craniocaudal images to assess the configuration of the fracture and to identify any other bony lesions (see Figure 13-3). Fractures have been classified into five types¹⁹:

- *Type 1.* Fractures of immature horses that involve the growth plate and the metaphysis. These are subdivided into type 1a, a nonarticular fracture involving only the growth plate, and type 1b, a Salter-Harris type II articular fracture involving the anconeal process and proximal part of the trochlear notch.
- *Type 2.* A simple articular fracture involving the middle of the trochlear notch.
- *Type 3.* A nonarticular fracture involving the proximal metaphyseal region.
- *Type 4.* Comminuted articular fractures.
- *Type 5.* A fracture involving the distal olecranon or ulnar shaft, extending proximally and entering the distal, nonarticular part of the trochlear notch.

A fracture that enters the trochlear notch should be examined carefully to determine whether it involves the articular or nonarticular portion. Treatment by internal fixation usually warrants a fair-to-good prognosis,²⁰⁻²³ provided that the fracture is identified early and unless comminution is excessive. Conservative management has also been successful if the fracture is not displaced; the best results are achieved with type 5 fractures.²⁴ If the horse is treated conservatively, healing should be monitored radiologically to ensure that no displacement has occurred. Potential complications of conservative management include nonunion, OA, development of a flexural deformity or contralateral laminitis, or development of an angular limb deformity in the contralateral limb.

Olecranon Bursitis

See Chapter 79 for a discussion of olecranon bursitis.

Humerus

Fractures of the Deltoid Tuberosity

Fracture of the deltoid tuberosity of the humerus occurs occasionally.^{5,25} Often no cause is identifiable, although in some horses trauma has been recognized. Lameness is acute in onset and moderate to severe, depending on the configuration of the fracture. Generally no soft tissue swelling is detectable, although deep palpation in the region may cause pain in acute, but not chronic, injuries. Turning on the limb induces pain. In the absence of localizing signs, nuclear scintigraphic examination may be the best indicator of the injury (Figure 40-8, A).

Diagnosis is by radiographic examination. A craniomedial-caudolateral oblique image is essential (Figure 40-8, B), because abnormalities may not be detectable in mediolateral images. Several configurations of fracture have been

Fig. 40-8 • A, Lateral scintigraphic image of the right shoulder of 7-year-old dressage horse with acute-onset, moderately severe lameness of 2 weeks' duration with no associated localizing clinical signs. There is marked focal increased radiopharmaceutical uptake in the region of the deltoid tuberosity of the humerus. Radiographic examination revealed an incomplete fracture line through the base of the tuberosity and slight periosteal callus. **B**, Craniomedial-caudolateral oblique radiographic image of the proximal aspect of the humerus of a 3-year-old Thoroughbred broodmare with acute-onset, severe right forelimb lameness. There is an incomplete fracture of the deltoid tuberosity of the humerus. The mare made a complete functional recovery, but a radiologically visible osseous cystlike lesion developed distal to the greater tubercle of the humerus.

identified: small chip fractures, single or comminuted, a longitudinal fracture through the tuberosity itself, and an incomplete oblique fracture extending proximocaudally through the humeral diaphysis and metaphysis. Conservative management results in a favorable outcome, unless an oblique fracture is displaced, for which internal fixation is recommended. The prognosis is good.

Stress Fractures

Stress fractures of the humerus are relatively common in young Thoroughbreds in training. Humeral stress fractures occur frequently in 3-year-old and older racehorses within 4 to 8 weeks of retraining, and in North America they are often seen from February to April. The most common locations are the proximocaudal aspect of the humerus and the distal cranial and caudal aspects.²⁶⁻²⁸ Unilateral lameness is usually acute in onset and relatively severe. This lameness often improves relatively rapidly with box rest. Despite preexisting callus formation indicative of previous ongoing bony reaction, previous lameness has often not been recognized. Usually no localizing signs are apparent, and the response to distal limb nerve blocks is negative. Nuclear scintigraphic examination is the most sensitive means of detecting a fracture and should be performed if a stress fracture is suspected on clinical grounds, because premature return to work may potentially result in a more

catastrophic fracture. A focal region of IRU is identified in the proximocaudal aspect of the humerus or the distal cranial or caudal aspects (Figure 40-9). Fractures are usually medial. Rarely there is a pattern of IRU consistent with an incomplete spiral fracture of the humeral diaphysis. Radiological examination is less sensitive, although in some horses new bone formation can be identified on the caudal aspect of the proximal epiphysis, sometimes with increased radiopacity of the subchondral bone or new bone on the cranial aspect of the distal metaphysis and physis. Identification of new bone associated with a distal caudal fracture is rare.²⁸ With treatment of box rest and controlled walking exercise for a minimum of 3 months, followed by a graduated return to work, the prognosis is good.

Fractures of the Greater or Lesser Tubercles

A fracture of the greater or lesser tubercle of the humerus is an occasional cause of unilateral forelimb lameness.^{6,29-33} The history is often unknown, and usually no localizing clinical signs are apparent. Lameness varies in degree. Intrathecal analgesia of the intertubercular bursa may improve the lameness. Although some fractures may be suspected on a mediolateral radiographic image, craniomedial-caudolateral oblique and cranioproximal-craniodistal (skyline) oblique radiographic images are often necessary. A caudolateral-craniomedial oblique image may be useful

Fig. 40-9 • Lateral scintigraphic images of the left (**A**) and right (**B**) elbows of 2-year-old Thoroughbred racehorse with acute-onset, severe left forelimb lameness that improved rapidly with rest. The image of the left elbow is reversed to facilitate comparison with the right. There is moderate, focal increased radiopharmaceutical uptake in the craniodistal aspect of the right humerus (*arrow*), compatible with a stress fracture. Radiographic examination revealed slight periosteal and endosteal callus on the craniodistal aspect of the humerus.

Fig. 40-10 • Transverse ultrasonographic image of the humeral tubercles and tendon of biceps brachii of a 2-year-old Thoroughbred filly with severe lameness at the walk. Lateral is to the right. There was slight soft tissue swelling in the shoulder region, but no focus of pain could be identified. Nuclear scintigraphic examination revealed marked focal increased radiopharmaceutical uptake in the humeral tubercles. There were no radiological abnormalities. Cortical disruption (*arrow*) is apparent.

to highlight a fracture of the cranial aspect of the greater tubercle.^{5,30} Fracture fragments may also be accurately localized using diagnostic ultrasonography²⁹ and in some horses are detectable only ultrasonographically (Figure 40-10). The overlying intertubercular bursa and tendon

of biceps brachii should be inspected carefully. Small fractures may be removed surgically. Endoscopy of the intertubercular bursa permits reasonable access to the greater tubercle but not the lesser tubercle.²⁹ Outcome is usually favorable.

Diaphyseal Fractures

Diaphyseal fractures of the humerus usually result from a fall or other traumatic incident and may be oblique, spiral, or severely comminuted. Lameness is acute in onset and severe, associated with considerable swelling, pain, and crepitus. The horse may stand with the elbow dropped, slight carpal flexion, and the weight only on the toe. Radial nerve paralysis may occur concurrently (see pages 144 and 474). The diagnosis is usually obvious, and the prognosis is poor, so humane destruction is justified.³⁴ Successful repair may be achieved in selected horses younger than 3 years of age.³⁵ Conservative management in foals with diaphyseal fractures is a reasonable choice, but breakdown of soft tissues and angular limb deformities of the contralateral limb are potential complications.

Proximal Physeal Injuries

Injuries of the proximal humeral physis are rare, but Salter-Harris type I and II fractures have been seen in horses younger than 2 years of age.³⁶ The prognosis with conservative management is poor.

Enostosis-like Lesions (Bone Islands)

Enostosis-like lesions, or solitary bone islands, have been recognized only since the advent of nuclear scintigraphy (see Chapters 19 and 39). An *enostosis* is defined as bone developing within the medullary cavity or on the endosteum, resulting in an area of increased radiopacity. In the horse, enostosis-like lesions have been described as focal or multifocal intramedullary sclerosis in the diaphyseal region

of long bones, near the nutrient foramen, often developing on the endosteal surface of the bone. The cause of these lesions is unknown. Such endosteal reactions must be differentiated from endosteal callus secondary to a stress fracture. The presence of such radiopaque lesions is not always associated with lameness.

In the humerus, enostosis-like lesions occasionally cause acute-onset, moderate-to-severe lameness in young Thoroughbreds and older athletes, but they may be present asymptotically. Usually no localizing clinical features are present. Lameness resolves relatively rapidly with rest, thus mimicking the behavior of horses with a stress fracture and therefore warranting nuclear scintigraphic examination. A region of intense IRU occurs in the distal caudal aspect of the humerus, distinguishable from a stress fracture because of its slightly more proximal and medullary location (Figure 40-11, A). Radiological examination usually reveals a relatively large, oval-shaped opacity within the medulla, adjacent to the nutrient foramen (Figure 40-11, B). However, initial radiological evaluation may be negative. Because lesions may be present asymptotically, it is important to rule out other potential causes of lameness.

Treatment is similar to that for a horse with a stress fracture: box rest and controlled walking exercise for approximately 3 months. An area of increased radiopacity may persist radiologically. Follow-up scintigraphic evaluation sometimes reveals normal radiopharmaceutical uptake, although in some horses there is persistent IRU despite resolution of lameness. The prognosis is usually

good, although occasionally horses have lesions in several limbs and lameness may shift from limb to limb.

Scapulohumeral Joint

Osteochondrosis

Osteochondrosis of the scapulohumeral joint is often clinically evident in the first year of life, but in some horses it is not manifested until the horse is 2 to 5 years of age, although periods of unexplained lameness may occur. Delayed-onset lameness is often associated with relatively subtle radiological changes, which are more localized compared with those in horses that have lameness evident earlier. Lameness is often acute in onset and moderate to severe and is generally characteristic of proximal limb lameness. Often the foot of the most severely affected limb rapidly becomes more upright and boxy. In young, immature athletic horses radiological changes are often present bilaterally, although clinical signs may be evident only unilaterally. Intraarticular analgesia usually results in improvement in lameness rather than complete alleviation; therefore the clinical significance of lesions in the contralateral limb can be difficult to interpret.

Radiological abnormalities involve the glenoid cavity of the scapula, the humeral head, or both and include flattening of the articular surfaces, resulting in loss of congruity of the articular surfaces, irregular lucent zones in the subchondral bone, modeling of the ventral angle of the scapula, and blurring of the normally sharp outline of

Fig. 40-11 • Lateral scintigraphic (A) and mediolateral radiographic images (B) of the left humerus of 3-year-old Thoroughbred filly in race training with left forelimb lameness of 3 weeks' duration. The lameness was not altered by local analgesic techniques. **A**, The nuclear scintigraphic image shows a region of intense focal increased radiopharmaceutical uptake in the distal diaphyseal region of the humerus, proximal to the usual site of stress fractures. **B**, There is a well-circumscribed area of increased radiopacity (arrows) adjacent to the principal nutrient foramen. This is an enostosis-like lesion. Lameness resolved after 2 months of box rest, and the lesion was scintigraphically silent, although there was no change in radiological appearance. The horse remained sound when returned to training.

Fig. 40-12 • A, Mediolateral radiographic image of the scapulohumeral joint of an 8-month-old Thoroughbred colt with severe left forelimb lameness. Radiolucent areas in the subchondral bone of the distal scapula and increased radiopacity and modeling of the glenoid cavity and ventral angle of the scapula are compatible with osteochondrosis. The humeral head also has variable radiopacity. **B**, The same horse 15 months after surgical debridement. The horse was sound. Substantial modeling of the glenoid cavity of the scapula has occurred. The horse trained and raced.

Fig. 40-13 • Craniomedial-caudolateral oblique image of the scapulohumeral joint of a 3-year-old Thoroughbred with lameness alleviated by intraarticular analgesia of the scapulohumeral joint. A well-defined depression in the proximal articular surface of the humerus is compatible with mild osteochondrosis (arrow). This was the only detectable radiological abnormality. With repeated intraarticular medication the mare raced successfully, winning several more Group 1 races.

the glenoid cavity, because of modeling of the articular margins (Figures 40-12 and 40-13). Generally a good correlation exists between the degree of lameness and the severity of radiological abnormalities. However, radiology may underestimate the degree of lesion severity.³⁶

If lameness is recognized in a horse younger than 18 months of age, conservative management usually results

in persistent lameness. Surgical treatment by radical arthroscopic debridement has resulted in some young horses being able to withstand race training, although their longer-term future has been poorly documented. In one study 45% of treated horses were able to return to athletic activity.³⁷ However, in another study only 15.4% of 26 potential racehorses started a race.³⁸ In some horses treated early, the bone shows a remarkable capacity to remodel (see Figure 40-12), whereas in others there is no change. Most horses show clinically significant improvement, even if lameness persists. However, surgical treatment in older horses is much less rewarding. In horses with minor radiological abnormalities, identified when in race training, periodic intraarticular medication with sodium hyaluronan and triamcinolone acetonide has permitted the horses to remain in training and race, although lameness has tended to recur. In weanlings and yearlings with moderate-to-severe lesions, conservative management, including stall rest, intraarticular injections of hyaluronan, and periodic radiological assessment of healing, has been successful.¹

Subchondral Bone Cysts and Other Osseous Cystlike Lesions

True subchondral bone cysts occur in the middle of the glenoid cavity of the scapula (Figure 40-14). Other osseous cystlike lesions have been identified less frequently in the humeral head. Subchondral bone cysts in the distal aspect of the scapula and other osseous cystlike lesions most commonly cause lameness in immature athletic horses, 1 to 3 years of age, but subchondral bone cysts in the distal aspect of the scapula have also been identified in much older horses with no prior history of lameness. Trauma may be an inciting cause. Lameness is usually acute in onset and moderate to severe. In some horses the lameness varies extremely, within and between examination periods, from barely detectable at any gait to obvious at the walk. Lameness is usually substantially improved by intraarticular

Fig. 40-14 • Mediolateral radiographic image of the scapulohumeral joint of 9-year-old hunter with episodic severe right forelimb lameness. There is a large, well-defined subchondral bone cyst in the middle of the distal scapula. The lameness responded to intraarticular medication with corticosteroids (triamcinolone).

analgesia of the scapulohumeral joint. However, interpretation can be extremely difficult in those horses that show marked spontaneous variations in lameness.

Small radiolucent zones are occasionally seen in the middle of the opaque band of subchondral bone of the glenoid cavity of the scapula in clinically normal horses and in the contralateral limb of horses with lameness associated with a large subchondral bone cyst in the distal aspect of the scapula. Lameness that is improved by intraarticular analgesia associated with such lesions but no other radiological change is seen infrequently.^{1,2,39} This has been correlated with defects in the articular cartilage extending into the subchondral bone.³⁹ More commonly a large circular or dome-shaped radiolucent area is seen, surrounded by a narrow rim of increased radiopacity. In some older horses in which such subchondral bone cysts have been identified, the cysts have been less well defined because they are less radiolucent. In skeletally mature horses similar lesions have occasionally been identified bilaterally associated with apparently unilateral lameness.

In skeletally immature horses subchondral bone cysts have been seen to enlarge progressively, and some appear to move proximally in the bone. Those identified in skeletally mature horses seem to persist unchanged. Osseous cystlike lesions in the proximal aspect of the humerus occur as circular radiolucent regions in the middle-to-caudal aspect. Some of these have been seen to fill in radiologically with time. Solitary subchondral bone cysts in the distal aspect of the scapula are generally not associated with any other detectable radiological change, whereas other osseous cystlike lesions are sometimes seen together with remodeling of the ventral angle of the scapula.

Nuclear scintigraphic examination may be helpful in horses in which lameness varies extremely in degree within an examination period. Subchondral bone cysts are associated with active bone modeling; therefore there is intense focal IRU.

Intraarticular medication of the scapulohumeral joint using hyaluronan and methylprednisolone acetate has been successful in resolving lameness in immature athletic horses, but results have been poorer in older horses.

Surgical treatment of subtle, small lucent zones has been successful,³⁹ but effective debridement of large lesions is impractical.

Osseous Cystlike Lesions in the Humeral Tubercles

Osseous cystlike lesions in the humeral tubercles are discussed on page 471.

Osteoarthritis in Miniature Breeds

Sudden-onset, severe lameness is sometimes seen in Shetland and Falabella ponies and Miniature horses.⁴⁰ Dysplasia of the joint predisposing to instability may be a predisposing factor for OA in some.^{40,41} Usually no known history of previous lameness or trauma exists. Lameness is typical of proximal limb pain. Manipulation of the shoulder may cause pain. Lameness is improved but rarely alleviated by intraarticular analgesia. Radiological examination sometimes reveals evidence of advanced OA, including periarticular osteophyte formation, and modeling of the ventral angle of the scapula (Figure 40-15). Occasionally, fragmentation of the ventral angle of the scapula occurs. Often new bone forms on the distal caudal border of the scapula and the proximal caudal aspect of the humerus in the regions of attachment of the joint capsule. In some ponies the contour of the glenoid cavity of the scapula appears flattened (see discussion of dysplasia on page 468), resulting in loss of congruity between the distal aspect of the scapula and the humeral head. In ponies with less severe abnormalities, radiological abnormalities may be detectable only in a craniomedial-caudolateral oblique image. In those ponies with minor radiological change at the time of onset of clinical signs, changes tend to have been rapidly progressive.

Arthroscopic evaluation of the joint reveals extensive softening of the articular cartilage, and surgical debridement has resulted in some clinical improvement, although lameness has persisted. The prognosis for athletic function is guarded. Surgical arthrodesis has been described.⁴²

Osteoarthritis in Nonminiature Breeds

OA in the scapulohumeral joint is relatively uncommon,³⁶ except as a sequela to osteochondrosis, an intraarticular fracture, or a tear of the scapulohumeral joint capsule. Lameness is mild to moderate and is usually improved by intraarticular analgesia, but false-negative responses do occur. Radiological abnormalities include loss of congruity between the glenoid cavity of the scapula and the humeral head, because of flattening of the humeral head or modeling of the ventral angle of the scapula; periarticular osteophyte formation, most easily seen on the cranial articular margins of the scapula; and radiolucent areas in the subchondral bone. The response to intraarticular medication is usually poor, and the prognosis for athletic function is guarded.

Care should be taken when evaluating the scapulohumeral joint arthroscopically, because widespread aging changes occur in the articular cartilage, especially of the distal aspect of the scapula.² These include softening of the articular cartilage and extensive fissure formation

Fig. 40-15 • A, Mediolateral radiographic image of the scapulohumeral joint of a 4-year-old Shetland pony with acute-onset, severe lameness that improved with intraarticular analgesia. There is marked modeling of the ventral angle of the scapula, periosteal new bone formation, and generalized increased radiopacity of the distal aspect of the scapula caused by extensive new bone. **B,** Craniomedial-caudolateral oblique radiographic image of a scapulohumeral joint of 5-year-old Miniature horse. There is poor congruity between the glenoid cavity of the scapula and the humeral head. Note also the periarticular periosteal new bone (arrows).

Fig. 40-16 • Postmortem appearance of the glenoid cavity of the scapula of an 8-year-old Thoroughbred with no history of lameness. There is modeling of the articular margin (arrows), and the articular cartilage appears irregular. This was bilaterally symmetrical and is a typical normal finding in mature horses.

(Figure 40-16). Modeling changes of the articular margins of the glenoid cavity of the scapula may also occur.

Tearing of the Scapulohumeral Joint Capsule

Localized tearing of the scapulohumeral joint capsule is an unusual cause of lameness that is improved by intraarticular analgesia. In the acute stage no detectable radiological abnormalities may be apparent, but with more chronic lameness enthesioid new bone may be seen in the region of damage. Nuclear scintigraphic examination may reveal focal or more generalized IRU in the region of the scapulohumeral joint. Although ultrasonographic examination may be helpful if the lesion is lateral, medial lesions cannot

be seen. Definitive diagnosis is based on diagnostic arthroscopy of the scapulohumeral joint. The prognosis for recovery for athletic function is guarded.

Dysplasia

Dysplasia of the scapulohumeral joint has been identified in Shetland ponies⁴¹ and Miniature horses,¹ sometimes together with subluxation of the joint or with OA (see the earlier discussion of OA in miniature breeds, page 467). Flattening of the radius of curvature of the glenoid cavity of the scapula occurs.

Luxation

Luxation of the scapulohumeral joint has been seen in ponies² more frequently than in horses and results in acute-onset, severe lameness associated with extensive swelling in the shoulder region (Figure 40-17, A). If the humerus has luxated laterally, the scapular spine is less easy to palpate than usual. The horse is reluctant to bear full weight on the limb at rest and is usually non-weight bearing at the walk. Diagnosis is confirmed by radiographic examination (Figure 40-17, B). Mediolateral and craniomedial-caudolateral oblique images should be obtained to determine whether a concurrent fracture is present and whether the luxation is medial or lateral. The humerus can luxate cranioproximally or caudoproximally.

A horse with simple acute luxation, without any concurrent fracture, can be treated by manual reduction of the luxation with the horse under general anesthesia in dorsal recumbency. A hobble is placed around the distal aspect of the affected limb, and the limb is maximally extended vertically. Pressure is applied to the shoulder region to reduce the luxation. An assisted recovery from general anesthesia is recommended, followed by cross-tying to prevent the horse from lying down, minimize the risks of reinjury, and allow the traumatized joint capsule to heal. Periarticular fibrosis inevitably develops, and treating the

Fig. 40-17 • A, An 8-year-old pony gelding with acute-onset, severe right forelimb lameness associated with swelling in the shoulder region. **B,** Mediolateral radiographic view of the scapulohumeral joint showing cranioproximal luxation of the humerus. The luxation was successfully reduced with the pony under general anesthesia, and the pony made a complete functional recovery.

horse with nonsteroidal antiinflammatory drugs and a controlled exercise program to restore normal joint mobility may be necessary. A complete functional recovery has been achieved in a small number of ponies. The presence of any concurrent fracture predisposes to recurrent luxation and warrants an extremely guarded prognosis. Persistent luxation results in the rapid development of a deep groove in the humeral head, extending from cranially to caudally; thus the prognosis is poor.²

Fracture of the Articular Surface of the Scapula or the Proximal Aspect of the Humerus

Fracture of the articular surface of the scapula may result from a fall when the horse is jumping, resulting in acute-onset, severe lameness.⁴³ Manipulation of the joint may produce pain, and sometimes crepitus can be elicited. Periarticular soft tissue swelling occurs in the acute stage, but this resolves relatively rapidly. Diagnosis requires high-quality radiographs, because the only detectable radiological abnormality may be loss of clarity of the articular margins of the distal aspect of the scapula. Mediolateral and craniomedial-caudolateral oblique images should be obtained. Follow-up radiographs may show modeling of

the ventral angle of the scapula. The prognosis for athletic function is hopeless.

Crushing of the caudal aspect of the humeral head has been seen as a result of a fall, resulting in acute-onset severe lameness. There may be no detectable radiological abnormality, but there is intense IRU in the humeral head. Severe lameness persists, yet follow-up radiographs may reveal only modeling of the ventral angle of the scapula. Post-mortem examination has confirmed the diagnosis.⁴⁴

Periarticular Trauma

Periarticular trauma—the result of a fall, collision between two horses, or collision between a horse and a solid object—may result in sudden-onset, severe, unilateral forelimb lameness because of severe bruising. Extensive periarticular soft tissue swelling may develop rapidly, with pain on deep palpation. In the acute stage determining whether a concurrent fracture is present may be difficult, especially fracture of the supraglenoid tubercle of the scapula or the first rib, because history and clinical signs are so similar.

If damage is restricted to bruising, lameness generally rapidly improves over the following 7 days. However, if concurrent trauma to the suprascapular nerve or its branch to the infraspinatus muscle occurred, clinically significant

neurogenic atrophy of the supraspinatus or infraspinatus muscles may occur within 7 days (see page 473). If moderate-to-severe lameness persists, then radiographic examination is indicated. If damage is restricted to soft tissue structures, then treatment with nonsteroidal antiinflammatory drugs combined with restriction to box rest and controlled exercise usually results in a rapid and complete recovery.

Intertubercular Bursa

Congenital abnormalities of the bicipital apparatus are a rare cause of lameness, sometimes not recognized until maturity.⁴⁵ Lameness is characterized by a shortened cranial phase of the stride at both the walk and the trot. Affected horses have generalized atrophy of the shoulder musculature or specifically of the biceps brachii, and abnormal prominence of the point of the shoulder. Contraction of the ipsilateral foot is probably a reflection of a chronic problem, despite reported acute onset of lameness. It may occur unilaterally or bilaterally. Mediolateral and cranio-proximal-craniodistal oblique radiographic images should be obtained. Abnormalities include absence of a lesser tubercle of the humerus, narrowing of the groove between the greater and intermediate tubercles, and evidence of OA of the scapulohumeral joint, probably the result of instability. Ultrasonography reveals either complete medial displacement of the tendon of biceps brachii or an abnormal shape and position of the tendon.

Rupture of the Tendon of Biceps Brachii

Rupture of the tendon of biceps brachii is a rare injury sustained as the result of a fall while jumping at speed.⁴⁶ It results in severe lameness at the walk, associated with diffuse soft tissue swelling around the shoulder. Diagnosis is based on radiographic and ultrasonographic examinations. The tendon may rupture through the isthmus between the medial and lateral lobes. The prognosis is hopeless.

Tendonitis of Biceps Brachii

Injury of the tendon of biceps brachii is a relatively uncommon cause of forelimb lameness, with no typical history. Frequently no localizing signs suggest the source of pain. In some horses forced retraction of the limb induces discomfort, but this is an unreliable finding. Lameness varies from mild to severe, and only if lameness is severe are the gait characteristics typical of proximal limb lameness. In some horses lameness is more obvious in the walk than at any other pace. Lameness is usually improved by intrathecal analgesia of the intertubercular bursa, although it may take up to half an hour. Some false-negative results occur in association with severe lesions.⁴⁴

Diagnosis is based on ultrasonographic examination. The entire length of the tendon of biceps brachii should be examined carefully from its origin on the supraglenoid tubercle of the scapula to the musculotendonous junction. The horse should be standing fully load bearing on the limb to avoid hypoechoic artifacts within the tendon. It is important to be aware of the anatomy of the tendon, which changes in shape from proximally to distally.^{8,10} Examining the medial and lateral lobes independently is often necessary, because maintaining both lobes in focus simultaneously is difficult. The tendon should be examined in transverse and longitudinal planes and careful

comparison made with the contralateral limb. Ultrasonographic abnormalities include enlargement of the tendon, loss of definition of one of its margins, hypoechoic defects within the tendon, and loss of fiber pattern in longitudinal images. The humeral tubercles should be inspected carefully for evidence of any concurrent damage. Concurrent evidence of bursitis characterized by an abnormal amount of fluid within the sheath (bursa) may also be present and results in an increased anechogenic space between the tendon and the humerus. Horses with chronic lameness may show evidence of hyperechogenic foci within the tendon, representing fibrosis, mineralization, or ossification. Adhesions may develop between the tendon and the wall of the bursa. Occasionally, echogenic bodies are seen free within the bursa.

Treatment of horses with tendonitis of biceps brachii consists of box rest and controlled walking exercise.⁴⁷ Injection of hyaluronan may be beneficial. The tendon should be monitored by ultrasonography at up to 3-month intervals. At least 6 to 9 months of convalescent time are required for horses with acute lesions, which have a fair prognosis. The prognosis for horses with chronic injuries is poor. Permanent enlargement of the tendon within the confined space between the brachiocephalicus muscle and the humerus and loss of normal gliding function cause persistent pain. Tenectomy or tenotomy has been described.⁴⁸

Osteitis of the Humeral Tubercles

Osteitis of the humeral tubercles is a rare cause of forelimb lameness.³¹ Horses show moderate-to-severe lameness and resent manipulation of the shoulder. Abnormalities of the humeral tubercles are seen radiologically as lucent areas or by ultrasonography as a roughened surface to the bone and overlying cartilage. The intertubercular bursa may contain an abnormal amount of fluid and the tendon of biceps brachii may be enlarged, with peritendonous reaction. Surgical exploration may reveal necrotic areas of bone that are readily debrided, resulting in improvement in lameness.

Fracture of the Humeral Tubercles

A discussion of fracture of the humeral tubercles appears on page 463 (see [Figure 40-10](#)).

Infection

Infection of the intertubercular bursa occasionally causes acute-onset, moderate-to-severe forelimb lameness.⁴⁹⁻⁵¹ Infection may be a sequela to known trauma, a previous injection, and a penetrating wound, but it has been recognized with no history of trauma or evidence of a wound, presumably infection being hematogenous in origin. Infection occurs in immature athletic horses and older horses.

The horse may stand slightly favoring the lame limb. Deep palpation in the region of the bursa may elicit pain. Retraction of the limb is resented. Lameness is often evident at the walk. Synovial fluid withdrawn from the bursa is usually grossly brown discolored and turbid, and therefore intrathecal analgesia is usually unnecessary. Diagnostic ultrasonography reveals an abnormal amount of fluid within the bursa; sometimes echogenic material is seen within the fluid, and the surface of the tendon of biceps brachii may be less well defined than normal because of

fibrin deposition. Diagnosis is confirmed by measuring differential white blood cell count and total protein concentration and by cytological examination of the synovial fluid, with polymorphonuclear leukocytes dominating.

Treatment is by radical surgical debridement and thorough lavage of the bursa by open surgery⁴⁹ or endoscopy,⁵⁰ combined with long-term, broad-spectrum antimicrobial therapy (e.g., crystalline penicillin and gentamicin) and the use of nonsteroidal antiinflammatory analgesic drugs. If a penetrating wound is identified, consideration should be given to using metronidazole. When the acute inflammatory response has subsided, controlled exercise is important to try to limit adhesion formation. If the condition is recognized and treated early and aggressively, a favorable outcome can be achieved, but prolonged therapy is often required.⁴⁹

Noninfectious Bursitis

Noninfectious bursitis does occur occasionally alone, together with tendonitis of biceps brachii (see page 470), or with osteitis of the humeral tubercles.^{6,52} Lameness varies in degree and is usually substantially improved by intrathecal analgesia. Diagnosis is verified by ultrasonographic examination of the intertubercular bursa. The bursa has an abnormal amount of fluid but no abnormalities of the enclosed tendon or the humeral tubercles. Treatment by intrathecal administration of hyaluronan and triamcinolone acetonide, combined with controlled exercise, is usually successful.

Mineralization

Mineralization or ossification within the tendon of biceps brachii has been seen alone, or as a sequela to a previous fracture of the supraglenoid tubercle.^{1,53} Ectopic mineralization within the bursa has been associated with substantial proliferation of the synovial membrane of the intertubercular bursa.⁹ No typical history is known. Lameness varies in degree and only if moderate to severe is typical of a proximal limb lameness. Lameness may be improved by intrathecal analgesia of the intertubercular bursa. Mineralization may be identified radiologically, but it can be obscured by the humeral tubercles. Radiography is useful to identify any previous fracture. There may be associated IRU.⁵³ Diagnostic ultrasonography provides more accurate information about the precise site and extent of mineralization and any concurrent pathological condition of the tendon. The prognosis for return to full athletic function is guarded.

Osseous Cystlike Lesions in the Humeral Tubercles

Osseous cystlike lesions in the humeral tubercles may develop secondary to trauma such as a fall or change in biomechanics resulting from other causes of lameness, or they may arise from an unknown cause.^{44,54-56} There is acute-onset moderate-to-severe lameness, usually with no localizing clinical signs. There is often no or limited response to either intraarticular analgesia of the scapulohumeral joint or intrathecal analgesia of the intertubercular bursa. Either lesions are identified using survey radiology or their presence is highlighted by scintigraphic evaluation demonstrating focal moderate-to-intense IRU. Lesions are sometimes not evident on mediolateral radiographs but may be seen in craniomedial-caudolateral oblique images.

If a lesion involves the cortex of the tubercle, osseous and cartilage defects may be identified using ultrasonography. In some horses there are also lesions in the biceps brachii tendon. Lameness has generally resolved with rest, with or without medication of the intertubercular bursa, although a radiolucent lesion may persist. Successful surgical treatment has also been described.⁵⁵

Scapula

Fracture of the Supraglenoid Tubercle

The scapula has four centers of ossification: the scapular cartilage, body of the scapula, cranial part of the glenoid cavity of the scapula, and supraglenoid tubercle. The cranial part of the glenoid cavity of the scapula fuses with the body by 5 months of age. The physis of the supraglenoid tubercle closes at 12 to 24 months of age. Fracture of the supraglenoid tubercle of the scapula is a relatively common injury, resulting from a collision with a solid object or fall. Fractures frequently occur through the original physes.⁴³ The fracture may be simple or comminuted, involving only the supraglenoid tubercle, without an articular component. Alternatively, the fracture may pass through the glenoid notch of the scapula, which may result in one large fracture or separation of both original physes.

Lameness is sudden in onset and moderate to severe. Over the first week the horse may show progressive improvement, but lameness persists. Neurogenic atrophy of the supraspinatus and infraspinatus muscles may develop within 7 days if a concurrent injury of the suprascapular nerve occurred. Disuse atrophy develops more slowly.

A palpable thickening in the region of the supraglenoid tubercle exists, but crepitus is rarely appreciated.

Diagnosis is confirmed radiologically (see Figure 13-1). The fracture fragments are often displaced craniodistally, because of the pull of the biceps brachii, and if treated conservatively a nonunion develops. The radiographs should be inspected carefully to determine if the fracture has an articular component, which warrants a more guarded prognosis. Rarely, there will be concomitant luxation of the scapulohumeral joint.

The prognosis with conservative treatment is poor for return to athletic function. Surgical treatment by removal of the fracture fragment(s) has been successful in some horses, although the level of work to which horses have returned has not been well documented. Various methods of internal fixation have been attempted, but the large distracting forces of biceps brachii have to be overcome. A small number of horses younger than 2 years of age and less than 400 kg body weight have been successfully treated by complete tenotomy of the biceps brachii and internal fixation using three 5.5-mm cortical bone screws.⁵⁷ Alternatively, in foals, yearlings, and small horses, the fracture can be repaired using a tension band technique with either a small plate or screws, preserving the biceps tendon.

Stress Fractures

Stress fractures of the body of the scapula are an occasional cause of acute-onset forelimb lameness in young Thoroughbreds in training.^{1,58,59} Usually no localizing clinical signs are present, although occasionally focal pain can be identified. Lameness often frequently improves spontaneously

with rest. A premature return to training may result in a catastrophic fracture. Scintigraphic examination reveals IRU in the mid-to-distal aspect of the scapula. Occasionally a fracture can be confirmed using ultrasonography. Treatment requires 6 to 8 weeks of box rest and controlled walking exercise, followed by a graduated return to full work. In my experience the prognosis has been good, but in a report from North America two of seven horses (29%) that resumed training had recurrent injury.⁵⁹

Fracture of the Body of the Scapula

Fractures of the body of the scapula usually result from the horse falling at a fence when jumping at speed. Complete fractures result in severe lameness and extensive soft tissue swelling and merit destruction on humane grounds. Diagnosis is usually obvious based on clinical signs, and radiographic examination is not necessary. Radiography or scintigraphic examination is required for the diagnosis of incomplete fractures (Figure 40-18). High-quality radiographs are required, and this may be difficult because the horse may resent protraction of the limb because of pain. Horses with fractures that enter the scapulohumeral joint have a poor prognosis. However, horses with extraarticular, incomplete fractures of the body of the scapula have a good prognosis for return to full athletic function with conservative management.

Fracture of the Scapular Spine

Fractures of the scapular spine result from a fall, collision with a solid object, or occasionally a kick. Acute-onset, moderate lameness occurs with associated localized soft tissue swelling and pain on palpation. Oblique radiographic skyline views of the scapular spine are necessary to identify a fracture. Diagnostic ultrasonography may be more helpful in identifying a fracture. Most horses with fractures heal adequately with conservative management. Occasionally a sequestrum develops, necessitating surgical

Fig. 40-18 • Mediolateral radiographic image of 7-year-old event horse with acute-onset, severe left forelimb lameness after a fall. There is an incomplete fracture of the body of the scapula. The horse was treated conservatively and made a complete recovery.

debridement. The prognosis for return to full athletic function is good.

Infection of the Infraspinatus Bursa

Injury of the infraspinatus bursa and tendon seldom occur except as a result of a penetrating injury in the shoulder region, resulting in infectious bursitis.⁶⁰ Signs include generalized swelling in the shoulder region, pain on manipulation of the shoulder, and lameness characterized by a shortened cranial phase of the stride. Ultrasonography reveals distention of the infraspinatus bursa with echogenic fluid, with thickening of the synovium if chronic. Evaluation of the greater tubercle of the humerus may reveal roughening or a fracture. Treatment includes lavage of the bursa, surgical debridement if indicated, and broad spectrum antimicrobial therapy. The prognosis is good.

Muscle

Triceps Myopathy

See Chapter 83 for a discussion of triceps myopathy.

Muscle Lesions: Brachiocephalicus, Biceps Brachii, and Pectorals

Lesions of muscles in the shoulder region have not been well documented and probably occur more commonly than recognized. However, clinical signs are rather nonspecific, and diagnosis is difficult. A number of dressage horses have been identified that have shown forelimb lameness only while performing lateral work. Palpation has revealed no detectable abnormality. Local analgesic techniques have not altered the lameness. Ultrasonographic examination has revealed hyperechogenic areas of fibrosis or mineralization within the brachiocephalicus in the lame limb only.

A dressage horse showed lameness only at the walk. Local analgesic techniques were ineffective. Nuclear scintigraphic evaluation revealed focal moderate IRU in the musculature cranioproximal to the elbow. This correlated with a hyperechogenic region within the biceps brachii.

Some horses have forelimb lameness associated with palpable soreness of the pectoral muscles, which responds well to physiotherapy. Soreness of the brachiocephalicus muscles is often seen with lameness caused by distal limb pain. Lameness is sometimes seen associated with primary brachiocephalicus muscle damage in dressage horses, show jumpers, event horses, and horses that race over fences. In most horses with acute lameness, palpation reveals muscle soreness and induces muscle spasm. However, in horses with chronic muscle injury pain can be more difficult to identify. In some horses lameness was evident only in walk and was characterized by lifting of the head and neck as the ipsilateral limb was protracted.

Rupture of Serratus Ventralis

The serratus ventralis muscles arise from the third to seventh cervical vertebrae and the first eight to nine ribs and insert on the medial proximal aspect of each scapula. They sling the thorax between the forelimbs. Rupture of one or both of these muscles is a rare injury, caused by trauma. The proximal border of the scapula moves proximally. If rupture is bilateral, the scapulae become higher than the summits of the dorsal spinous processes in the withers region. Rupture of the serratus ventralis should be

differentiated from neurological disease causing loss of function of the muscle.¹

The horse tends to stand with the forelimbs close together. Palpation of the withers region or manipulation of the forelimbs causes pain. The horse is reluctant to move, takes small steps, and nods the neck stiffly.

Radiographic examination should be performed to rule out a fracture of the scapula or the dorsal spinous processes of the cranial thoracic vertebrae. The prognosis for athletic function is poor.

Nerve

Atrophy of Supraspinatus and Infraspinatus Muscles: Damage to the Suprascapular Nerve

The suprascapular nerve wraps around the cranial aspect of the neck of the scapula and in this position is vulnerable to trauma resulting in perineural edema, stretching, and neuroma formation. Neuroma formation usually results in permanent loss of function and subsequent neurogenic atrophy of supraspinatus and infraspinatus muscles. This can occur within 7 days of injury. Atrophy results in abnormal prominence of the scapular spine, but damage to the suprascapular nerve alone does not result in any loss of stability of the scapulohumeral joint. Lameness may be the result of trauma at the time of the injury but generally resolves rapidly, unless a concurrent fracture is present.

This condition has been called *Sweeny*, but this can be confusing because this term has also been used to describe instability of the shoulder or shoulder slip resulting from loss of collateral support of the shoulder musculature. This latter condition is separate and should not be confused (see the following discussion). Experimental transection of the suprascapular nerve in two ponies and one adult horse resulted in rapid atrophy of the supraspinatus and infraspinatus muscles, which persisted over the long term but produced no gait abnormality.²

The injury usually results from a fall or collision with another horse or solid object. Permanent muscle atrophy may ensue, but this results only in a cosmetic defect, not a functional deficit. Electromyography can be used to determine whether any other muscles are affected, which would suggest an injury to the brachial plexus or to other nerves in addition to the suprascapular nerve. Patchy sweating indicates a lesion elsewhere.

Surgical treatment has been performed to decompress the suprascapular nerve by cutting out a notch on the craniodistal aspect of the scapula and removing fibrotic material from around the nerve.⁴⁴ Surgical treatment has resulted in restoration of more normal muscle mass.⁶¹ Care must be taken not to traumatize the scapula unduly, because this may predispose to fracture.

Instability of Shoulder: Damage to the Brachial Plexus

Lack of collateral support to the scapulohumeral joint by loss of function of the muscles on the medial (subscapularis) and lateral aspects of the joint results in so-called *shoulder slip*. As the horse starts to bear weight on the limb, the shoulder joint bulges abaxially (Figure 40-19; see Figure 6-19). Concurrently the heel of the foot tends to rotate outward. This gait abnormality is evaluated most easily viewing the horse walking toward the observer. The gait abnormality may be slight or severe.

Fig. 40-19 • A 7-year-old driving pony with acute-onset instability of the left shoulder joint probably caused by a brachial plexus injury. The injury was of 12 days' duration. Note the medial placement of the left front foot. The heel rotated laterally as the foot broke over. There was moderate atrophy of the left infraspinatus, supraspinatus, and triceps muscles. The pony was treated conservatively, progressively improved, and made a complete functional recovery.

Instability of the shoulder was formerly ascribed to atrophy of the supraspinatus and infraspinatus muscles secondary to suprascapular nerve damage, but profound atrophy of these muscles can be present with no detectable gait abnormality.^{2,11} Experimental transection of the suprascapular nerve has resulted in profound atrophy of supraspinatus and infraspinatus muscles but no detectable gait abnormality.² Seven horses with persistent instability of the shoulder that were humanely destroyed and examined post mortem had atrophy of at least the supraspinatus, infraspinatus, and subscapularis muscles. All horses had neuroma formation involving nerves of the brachial plexus or the ventral nerve roots of the contributing nerves. The suprascapular nerve appeared normal as it passed over the cranial aspect of the scapula.

Instability of the shoulder invariably results from trauma, usually the horse colliding with a solid object. Pain-related lameness may also be present initially, but this generally resolves within 1 to 2 weeks, provided that a concurrent fracture does not exist. Similar clinical signs

occasionally occur transiently (for 1 to 3 hours) after intraarticular analgesia of the scapulohumeral joint, presumably because of extraarticular leakage of local anesthetic solution. Instability of the shoulder has also been seen in a Miniature horse with dysplasia of the scapulohumeral joint and advanced OA.

After trauma, initially no muscle atrophy is detectable, but atrophy of several muscles is usually detectable within 7 to 10 days. Patchy sweating may develop in the caudal neck region or over the scapula, depending on which nerves have been damaged. Electromyography can be used to determine accurately which muscles are affected.

Prognosis depends on the nature of the nerve damage and the ability to achieve reinnervation of the affected muscles. Nerve regeneration occurs at approximately 1 mm per day. Progressive improvement in gait is a good prognostic sign. A normal gait may be restored despite persistence of atrophy of the supraspinatus and infraspinatus muscles.^{2,62} However, a persistent gait abnormality 6 months after injury warrants a guarded prognosis. Surgical treatment is impractical because of the inaccessibility of the brachial plexus or the ventral nerve roots. Scapular notch resection is not indicated, because nerves in addition to or other than the suprascapular nerve are involved. This procedure also risks secondary fracture of the scapula.

Radial Nerve Paralysis

Radial nerve paralysis is an occasional cause of lameness.^{63,64} The clinical signs depend on the site or sites of damage. Complete radial nerve paralysis is most common, with loss of function of the extensor muscles of the elbow, carpus, and digit, and results in inability to stand on the limb. The elbow is dropped, and the horse tends to stand with the affected limb forward, with the antebrachium at an angle of approximately 45 degrees to the ground, with the carpus and fetlock semiflexed (see Figure 5-14). Less

commonly only the extensor muscles of the elbow are affected, so although the limb may be advanced forward, the elbow will drop during weight bearing. Occasionally only the extensor muscles of the carpus and digit are affected, so that the limb is advanced and placed normally, but then the carpus or fetlock may slightly knuckle forward. The horse has a tendency to stumble.

Lameness is usually sudden in onset. The horse may have a history of trauma. Paralysis occurs most commonly in young horses turned out together. Although damage to the radial nerve itself may be the cause of lameness,^{63,64} many injuries are probably caused by compression of the brachial plexus between the scapula and the ribs or can be associated with a fracture of the dorsal aspect of a rib involving the eighth cervical nerve. An electromyogram may demonstrate involvement of more than the radial nerve. Equine protozoal myelitis should be considered in older horses, especially if evidence of other lower motor neuron pathological conditions exists (see page 140).

Many horses make a slow progressive recovery. Electrical stimulation of the affected muscles may help to maintain muscle mass. Problems may arise in young horses with overload of the contralateral limb, unless symptoms resolve quickly. An improvement within 2 to 4 weeks warrants an optimistic prognosis. Persistence of clinical signs for more than 6 months warrants a guarded prognosis.

Fracture of the First Rib

Occasionally, acute-onset, severe lameness follows trauma from a fall or collision with a solid object associated with a fracture of the first rib. The lameness is typical of a proximal limb injury, but no other localizing signs are present. Atrophy of the infraspinatus alone has also been recognized in some horses. Diagnosis is by radiographic examination. Nuclear scintigraphic examination may facilitate diagnosis. The prognosis is good after rest.

The Hindlimb

Chapter 41

The Hind Foot and Pastern

Mike W. Ross

The contribution of the hind foot and pastern to hindlimb lameness is considerably less important than that of the digit to forelimb lameness. Extensive information regarding lameness of the foot and pastern in the forelimb is found in Chapters 26 to 35 and 82. This information is directly applicable to the hindlimb. During lameness examination, the hind foot and pastern are easily overlooked because they are in a potentially dangerous place to examine. Other regions of the hindlimb have been presumed to be more important, and, historically, little has been taught about the distal part of the limb. Without a commitment to performing diagnostic analgesic techniques in the distal aspect of the hindlimb, there is little way to discover whether the digit is the authentic source of pain unless the problem is severe or obvious. Subtle primary or compensatory lameness problems of this region are likely to go unnoticed daily. However, in certain sports horses, such as the draft horse, lameness of the hind foot and pastern is so common that this region cannot be overlooked. I am curious as to why infectious osteitis of the distal phalanx is more common in the hind feet. Of 26 affected limbs in 21 lame foals with infectious osteitis of the distal phalanx, most likely hematogenous in origin, 18 (69%) were hindlimbs.¹ Infectious arthritis in foals occurs more commonly in hindlimb joints, specifically the femoropatellar and tarsocrural joints, than in forelimb joints, a finding that is equally difficult to explain.²

ANATOMY AND INNERVATION OF THE HIND FOOT AND PASTER

The bones are essentially the same as in the forelimb. The hind distal phalanx is narrower compared with the forelimb and has a steeper dorsal angle. The plantar surface is more concave, and the plantar processes are closer together.¹ In external appearance, the hind foot usually is more upright than the fore foot, but abnormal wear and shoeing practices can produce a common pathological

condition of a low, underrun heel (see Chapter 6). The hind middle phalanx is narrower and longer, and the hind proximal phalanx is slightly shorter than the corresponding bones in the forelimb.³ The ligaments, tendons, digital flexor tendon sheath (DFTS), and distal interphalangeal and proximal interphalangeal joints are the same as in the forelimb. Innervation of the foot is derived primarily from the medial and lateral plantar nerves, which originate from the tibial nerve (see Chapter 10). The medial and lateral plantar metatarsal nerves, which originate from the deep branch of the lateral plantar nerve, become superficial just distal to the “bell” of the second and fourth metatarsal bones. Unlike the palmar metacarpal nerves, the hindlimb medial and lateral plantar metatarsal nerves supply sensation to the pastern region and coronary band, a fact that can complicate interpretation of perineural analgesia in the hind digit.⁴

EXAMINATION, CLINICAL SIGNS, AND DIAGNOSIS

The clinical examination of the hind foot and pastern was described in Chapter 6, and a detailed description of the clinical investigation of the foot and shoeing is found in Chapters 27, 28, and 30 to 34. A conscientious effort must be made during every lameness examination to evaluate the hind foot with the limb in both the standing and flexed positions. The type of shoeing and shoe wear are important in understanding potential lameness conditions of the foot, but perhaps more important, study of hind foot balance and shoeing can provide important clues in the diagnosis of lameness located more proximally in the limb. Dramatic abnormalities in balance and shoe additives, such as calks, grabs, trailers, and bars, can place added forces of shear and torsion on hindlimb bones and joints. Therapeutic recommendations cannot be made unless the clinician is aware of the type of shoes that are currently in place. Hoof imbalance has not been studied extensively in the hindlimb, but dorsal to plantar and medial to lateral hoof imbalance is a likely contributor to lameness in the proximal interphalangeal and metatarsophalangeal joints. Palpation for signs of inflammation, such as increased digital pulse amplitude, heat, swelling, and pain, must be performed but can be difficult in fractious horses. Palpation is difficult in the hindlimb because of the stay apparatus, which causes the digit to flex involuntarily. Palpation of the plantar pastern soft tissue structures is difficult, and subtle swelling and pain associated with the distal sesamoidean ligaments or other structures can be easily overlooked. In draft horses, signs of inflammation can be obscure (Figure 41-1).

Fig. 41-1 • The defect in the coronary band of this draft horse was not detected until the long hair (or feathers) was shaved. Hoof tester examination yielded negative findings, but investigation of the foot was prompted by a positive response to perineural analgesia.

Examination with hoof testers is important, but normally horses show considerable sensitivity across the heel (see Chapter 6). Because the foot is incorporated in the rigid hoof capsule and swelling may not be apparent, even severe lameness conditions, such as abscesses or fractures, can go unnoticed. Commonly lameness of the hind foot is misinterpreted as originating high up in the limb, because clinical signs are not prominent and are easy to overlook.

Degree of lameness varies greatly. Most recognized problems of the hind foot cause obvious, often severe lameness, but occasionally subtle or insidious problems occur. Horses with the most common problems, such as a hoof abscess and penetrating wounds, may not bear weight. If they are bearing weight, horses usually are severely lame at the trot. Horses with severe hind foot lameness, particularly of the toe region, may walk with a shortened *caudal* phase of the stride, similar to horses with pain in the coxo-femoral region (see Chapter 7). Horses with most lameness conditions typically have a shortened cranial phase of the stride at both the walk and trot. Observing a paradoxical shortened caudal phase of the stride at the walk and the more typically seen shortened cranial phase of the stride at the trot can be an indication of hind foot pain. The horse may bear weight only on the toe. Turning may accentuate pain. At the trot, horses with hind foot and pastern lameness travel like horses with pain that originates anywhere distal to the distal aspect of the crus, and no typical alteration in limb flight is observed. When the horse is viewed from behind, limb flight is characterized by moving the foot straight ahead or slightly medial to the line of expected limb flight and then stabbing laterally during the later portion of the stride, just before impact.

Lameness associated with many conditions in this region worsens with a lower limb flexion test. Horses with osteoarthritis of the distal interphalangeal and proximal interphalangeal joints or tenosynovitis of the DFTS and tendonitis of the deep digital flexor tendon (DDFT) respond prominently. In general, hindlimb flexion tests have low specificity, and in horses that respond markedly to lower limb flexion, a source of pain located more proximal in

the limb cannot be dismissed without using diagnostic analgesia.

Lameness must be localized using perineural or intra-articular analgesic techniques. Differentiation of sources of pain in the hind foot and pastern can be problematic because the same difficulties in interpretation of plantar digital and distal interphalangeal analgesic techniques occur as in the forelimb. When the plantar digital block is done with the limb elevated, it is difficult to inject local anesthetic solution just above the cartilages of the foot, so this block is usually performed in a more proximal location than in the forelimb. It may be difficult to remove all pain in horses with severe lameness. Pain associated with the proximal aspect of the proximal phalanx, such as from midsagittal fractures, or from other causes of pain in the metatarsophalangeal joint can easily be removed inadvertently during performance of plantar digital analgesia.⁵ Careful interpretation of analgesic techniques is necessary, particularly in racehorses, in which metatarsophalangeal joint region lameness is common (Figure 41-2).

Imaging considerations are similar to those described in the forelimb. It may be preferable to obtain plantarodorsal rather than dorsoplantar radiographic views of the foot. Many horses are reluctant to stand on a block with the foot bearing weight for lateromedial views. Satisfactory images can readily be obtained with the foot bearing weight only on the toe, provided that the foot is not rotated.⁶

SPECIFIC LAMENESS CONDITIONS

Overall the most common conditions of the hind foot and pastern involve hoof abscesses and bruises, penetrating wounds into the hoof capsule and soft tissues of the pastern region, and cellulitis. Scratches can cause horses to appear lame at a walk and when severe, lame also at the trot. Management of these conditions is well described elsewhere.

Fractures of the Distal Phalanx

Fractures of the distal phalanx occur in any type of sports horse as the result of direct trauma from kicking a wall or trailer. Occasionally horses step on a hard object while turned out or during competition. In racehorses, fractures of the distal phalanx can occur as a result of maladaptive or nonadaptive remodeling, but this is much less common than in the forelimb. Because many fractures are the result of direct trauma, the distribution varies. Of 72 racehorses with fractures of the distal phalanx, only nine fractures involved a hindlimb, but eight involved the medial aspect of the distal phalanx.⁷ Distribution of hindlimb distal phalangeal fractures differs markedly from that seen in the forelimb of racehorses, in which left front (LF) lateral and right front (RF) medial fractures are most common.⁷ Medial location seems counterintuitive if hindlimb distal phalangeal fractures share a common cause with those seen in the forelimb. In the forelimb it is proposed that many distal phalangeal fractures are stress fractures that occur as a result of chronic repetitive bone injury, and the distribution reflects a counterclockwise direction of racing, making the lateral side of the LF and medial side of the RF (compression side of bone) prone to the development of fracture.⁷ It is the distal lateral aspect of the hindlimb that appears prone to the development of other stress-related

Fig. 41-2 • A, Lateral delayed phase scintigraphic image of a 4-year-old Standardbred pacer with right hindlimb lameness thought to originate in the foot because the horse was sound after plantar digital analgesia. However, focal, intense increased radiopharmaceutical uptake of the proximal aspect of the proximal phalanx (arrow) is diagnostic for fracture. **B**, Dorsoplantar digital radiographic image documenting the presence of a short, midsagittal fracture of the proximal phalanx (arrow). Pain originating from the metatarsophalangeal joint can be desensitized by plantar digital analgesia.

subchondral bone injury (see Chapters 19, 42, and 106 to 109), and why the distribution of distal phalangeal fractures is different is unknown. Articular plantar process fractures are most common, but incomplete (stress) fractures and midsagittal fractures also occur. Lameness is variable in degree, and it is important to recognize that lameness may be episodic in horses with a nonarticular plantar process fracture. Fractures often can be seen in lateromedial radiographic images, but special oblique images may be required. Comminuted fractures are rare but develop as the result of direct trauma. An unusual fracture near the insertion of the DDFT was found in a 2-year-old Thoroughbred colt referred for scintigraphic examination for undiagnosed right hindlimb lameness (Figure 41-3). This horse raced successfully with conservative management and corrective shoeing. Conservative management in most horses with fracture of the distal phalanx is quite successful. The decision to perform neurectomy is often made earlier than for injuries in a forelimb.

Laminitis

In horses with enterocolitis, pleuritis, metritis, or other systemic diseases, laminitis can develop in all four limbs, but rarely is the condition seen in only the hindlimbs. Even when hind feet are involved, clinical signs usually are most prominent in the front feet. Laminitis restricted to the hind feet has been seen only in overweight cob-type horses and ponies.⁸ Traumatic laminitis can occur from intense exercise on hard ground in unshod horses, but it most commonly develops in the contralateral limb of horses with severe unilateral hindlimb lameness. In the latter form, called *orthopedic laminitis*, distal displacement or rotation

Fig. 41-3 • A, Lateral (left image), plantar (middle image), and solar (right image) delayed phase scintigraphic images of a 2-year-old Thoroughbred colt in race training referred because of undiagnosed right hindlimb lameness. Lameness improved but did not abate completely after plantar digital and low plantar analgesia. Focal, intense increased radiopharmaceutical uptake (arrows) is seen in an unusual location, near the insertion of the deep digital flexor tendon on the distal, central aspect of the distal phalanx. **B**, Dorsal 45° lateral-plantaromedial oblique digital radiographic image showing an unusual lesion thought to be a small fracture fragment (arrow).

Fig. 41-4 • A, Large wound in the left tarsal region as a result of inappropriate application of a topical counterirritant that caused chronic, severe lameness and eventually caused infectious arthritis of the distal hock joints. **B**, Photograph of the contralateral hind foot showing a noticeable convexity of the sole (*arrows*), the result of rotation and distal displacement of the distal phalanx (orthopedic laminitis).

of the distal phalanx generally takes considerable time to develop (5 to 8 weeks) and can go unrecognized for several weeks (Figure 41-4). Often the first clinical sign that a problem is developing in the contralateral (laminitic) limb is that the lameness is observed to be inexplicably considerably improved in the original limb, or the horse starts to constantly shift weight between the two hindlimbs. Rarely, I have observed hindlimb laminitis as an apparently incidental finding in horses referred for scintigraphic examination for primary forelimb lameness or when whole-body scintigraphic examinations are performed. Marked increased radiopharmaceutical uptake (IRU) involving the distal or dorsal aspect of the distal phalanx and radiological evidence of rotation were seen. Primary lameness is found elsewhere, but laminitis in these horses may represent an unusual form of compensatory lameness.

I have examined two pleasure horses with primary bilateral hindlimb laminitis (without forelimb involvement) in which an unusual hindlimb gait was observed. At the walk horses had a goose-stepping gait like that seen in horses with fibrotic myopathy. The horses appeared to be attempting to land with an exaggerated heel-to-toe hoof strike. Both horses had a marked shortening of the caudal phase of the stride. At the trot horses had a short, choppy gait, but because lameness was bilateral, overt unilateral signs could not be seen.

Keratoma

Keratoma involving the hind feet is rare. An unusual radiolucent defect thought to be a keratoma that caused lameness and poor racing performance and was associated with IRU has been seen in the distal phalanx of a Thoroughbred racehorse.⁹

Navicular Syndrome

Navicular disease, osseous cystlike lesions, fractures, and malformations of the navicular bone are unusual in the hindlimb but do occur in all types of horses and ponies

(see Chapters 30 and 31). In fact, in young racehorses, odd conditions of the navicular bone seem more common in the hindlimb than in the forelimb. The foot should never be discounted as a potential source of lameness (Figures 41-5 and 41-6). Degree of lameness is variable; lameness is usually unilateral and improved by perineural analgesia of the plantar digital nerves. Lesions are usually readily detectable radiologically. Lesions may occur bilaterally; therefore radiographic examination of both hind feet is recommended. It may be more difficult to obtain a skyline image of the navicular bone in a hindlimb than in a forelimb. Scintigraphy can be helpful in some horses, particularly in those suspected of having pain originating more proximal in the limb and fractious horses in which diagnostic analgesia to properly localize pain is dangerous.

Distal Interphalangeal Joint

Primary osteoarthritis of the hind distal interphalangeal joint is rare. Osteophytes involving the extensor process of the distal phalanx are commonly seen but are usually incidental radiological findings. Osteoarthritis occurs as a result of instability or incongruity caused by articular fractures of the distal phalanx. Occasionally subchondral bone damage of the articular surface of the distal phalanx occurs and is recognized as radiolucent defects and secondary osteoarthritic changes; this damage usually is seen in older nonracehorse sports horses. Chronic, undiagnosed hindlimb lameness is followed by acute, prominent lameness. Diagnosis may be difficult, thus prompting scintigraphic examination. Focal areas of IRU in the subchondral bone of the distal phalanx should be differentiated from those in horses with incomplete fracture.

Extensor process fragments or fractures are rare. Osseous cystlike lesions as a result of osteochondrosis of the distal phalanx are seen occasionally. Some small lesions restricted to the subchondral bone of the distal phalanx are difficult to identify radiologically but usually result in intense, focal IRU scintigraphically. Definitive diagnosis may be possible

Fig. 41-5 • A, Lateral (left image), plantar (middle image), and solar (right image) delayed (bone) phase scintigraphic images showing focal, moderately increased radiopharmaceutical uptake of the navicular bone in a 2-year-old, unraced Thoroughbred filly, admitted for examination of chronic right hindlimb lameness. **B,** Corresponding lateromedial digital radiographic image showing extensive degeneration of the navicular bone, with both bony proliferation and radiolucent defects present. There was no history of a penetrating wound or other traumatic incident, and an unusual malformation of the navicular bone was diagnosed. Note the close proximity of the distal aspect of the navicular bone to the distal phalanx, the abnormal orientation of the distal phalanx, and the abnormal shape of the hoof capsule.

only with magnetic resonance imaging (MRI) or at post-mortem examination.⁸ Other fractures involving the distal aspect of the middle phalanx and comminuted fractures of this bone occur. Involvement of the distal interphalangeal joint in horses with comminuted fractures of the middle phalanx is a negative prognostic finding.

Collateral ligament injury of the distal interphalangeal joint is an uncommon cause of hindlimb lameness but does occur, usually with no localizing clinical signs. Although occasionally lesions can be identified using ultrasonography, diagnosis usually requires MRI.

Deep Digital Flexor Tendonitis

Primary injuries of the DDFT are an unusual cause of hindlimb lameness but have been identified in show jumpers and event horses. There has been an acute onset of moderate-to-severe unilateral lameness, usually with no localizing clinical signs. Diagnosis usually requires MRI.

Infectious Osteitis in Foals

See Chapter 128.

Fig. 41-6 • Dorsal 65° proximal-plantaro(palmaro)distal oblique digital radiographic images of the left hind (LH) (A) and left fore (LF) (B) feet showing unusual, coexistent navicular bone fractures in a 3-year-old Standardbred filly pacer. Baseline 3 to 4 out of 5 LH lameness resolved after plantar digital analgesia, but the filly then showed marked LF lameness. Acute LH navicular bone fracture (arrows) with mild displacement and chronic LF navicular bone fracture or bipartite navicular bone anomaly (arrows) were diagnosed.

The Hind Pastern

Lameness of the hind pastern region includes osteoarthritis of the proximal interphalangeal joint, osseous cystlike lesions of the distal aspect of the proximal phalanx, osteochondral fragmentation of the proximal interphalangeal joint, subluxation of the proximal interphalangeal joint, tenosynovitis of the DFTS, tendonitis of the DDFT and the branches of the superficial digital flexor tendon, injury of the distal sesamoidean ligaments, penetrating wounds, and cellulitis (see Chapters 35, 70, 74, and 82). Fractures of the proximal and middle phalanges are discussed in detail in Chapter 35. One fracture type, Salter-Harris type II fractures of the proximal aspect of the proximal phalanx, occurs most commonly in the hindlimb. Because physeal fractures are inherently more stable than those of the diaphyseal region of long bones, it is compelling to simply apply external coaptation such as a fiberglass cast incorporating the foot. However, prolonged cast immobilization quickly causes flexor laxity in foals and can predispose to osteoarthritis and sesamoiditis. Invariably, even with inherent stability, fracture displacement occurs. The metaphyseal component is usually plantaromedial, and even with external coaptation the proximal fracture fragment shifts distally and plantarolaterally and a gap opens on the dorsomedial aspect. Internal fixation using screws placed from

Fig. 41-7 • Dorsal 45° medial-plantarolateral oblique digital radiographic images before (A) and immediately after (B) repair and 3 months after repair and implant removal (C) in a weanling Warmblood foal with a Salter-Harris type II fracture of the proximal aspect of the right hind proximal phalanx. Using the tension band principle, a three-hole, limited-contact dynamic compression plate was applied to the dorsolateral aspect of the proximal phalanx; the middle screw was placed in lag fashion through the metaphyseal component. Rigid internal fixation obviated the need for prolonged external coaptation and maintained fracture alignment.

the plantaromedially located metaphyseal portion improves stability, but alignment of the fracture is hard to maintain. An alternative approach is to apply a dorsolateral dynamic compression plate, a technique that takes advantage of the tension band principle, because the tension side of the

proximal phalanx appears to be dorsolateral when this fracture occurs (Figure 41-7). Rigid internal fixation obviates the need to maintain foals in external coaptation. Because the epiphysis is narrow, care must be taken when placing the proximal screw.

Chapter 42

The Metatarsophalangeal Joint

Mike W. Ross

Lameness of the metatarsophalangeal (MTP) joint is similar to that of the metacarpophalangeal joint, but historically it has largely been ignored and was mentioned only twice in a leading lameness textbook.¹ With fastidious use of both intraarticular and perineural analgesia, the MTP joint is now known to contribute substantially to hindlimb lameness.²

ANATOMY

The MTP joint is nearly identical to the metacarpophalangeal joint and is composed of the distal articular surface of

the third metatarsal bone (MtIII), its sagittal ridge, and the medial and lateral condyles; the medial and lateral proximal sesamoid bones (PSBs); and the proximal articular surface of the proximal phalanx, which has a prominent axially located sagittal groove (see Chapter 36). Minor differences exist in the shape and length of the proximal phalanx between the forelimbs and hindlimbs but are not clinically relevant. The MTP joint normally is more upright than the metacarpophalangeal joint and can achieve a greater degree of flexion. The lateral-to-medial width of the lateral condyle of the MtIII is less than that of the medial condyle. In racehorses, based on the results of scintigraphic examination, stress-related bone injury occurs predominantly in the lateral aspect of the hindlimb, which may be related to the smaller surface area of the lateral condyle. The joint capsule, intersesamoid and collateral sesamoid ligaments, suspensory ligament (SL) attachments, and digital flexor tendons all function to move and support the MTP joint. The dense collateral ligaments have short deep, and long superficial components. In the hindlimb the lateral digital extensor tendon joins with the long digital extensor tendon in the proximal dorsal metatarsal region. Therefore only the long digital extensor tendon is

encountered during arthrocentesis or surgical procedures performed in the dorsal aspect of the MTP joint.

CONFORMATION

Fetlock valgus and varus deformities affect the MTP joint in foals, but fetlock varus deformity is of most concern and needs to be corrected early (see Chapter 58). Most normal horses are slightly toed out in the hindlimbs, but in some horses toed-out conformation may play a role in uneven load distribution and affect hindlimb gait. Horses with toed-out conformation tend to travel close behind and stab laterally during limb advancement, a gait that may cause excessive lateral shoe wear and hoof imbalance. Such gait and hoof imbalance may predispose the lateral aspect of the MTP joint to stress-related bone injury. Horses that are excessively straight behind have an abnormal degree of extension (or dorsiflexion) of the MTP joint. This conformation is undesirable because it places abnormal load on the SL and predisposes to suspensory desmitis, stifle joint lameness, and secondary osteoarthritis (OA) of the MTP joint. Horses with bull-nose foot conformation and long, weak hind pasterns may be predisposed to injury (see Chapter 4, Figure 4-34). When viewed from behind when walking and trotting, some horses—especially those with a base-narrow conformation—appear to collapse laterally over each hind fetlock.

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF METATARSOPHALANGEAL JOINT LAMENESS

Lameness of the MTP joint occurs in most sports horses and is common in the racehorse. Both Standardbred (STB) and Thoroughbred (TB) racehorses are prone to injury of this joint, but MTP joint lameness is more common in the STB, because gait and load distribution predispose to hindlimb lameness in this breed (see Chapter 2). Lameness of the MTP joint should never be discounted in the TB racehorse, and in both the STB and TB racehorse in my referral practice, conditions of this joint are the most common cause of undiagnosed hindlimb lameness. Curiously, MTP joint lameness is apparently uncommon in Western performance horses despite the predominant use of the hindlimbs for many maneuvers and thus tremendous forces applied to the MTP joint (see Chapter 120). With Western performance horses, sporting activity may play a role because in barrel horses and team roping heading horses, lameness of the distal aspect of the hindlimb including the MTP joint was uncommon, but in team roping heeling horses, the MTP joint contributed substantially to lameness and poor performance.^{3,4} There is no pathognomonic historical information that incriminates the MTP joint more than other sources of hindlimb lameness, but racehorses are usually worse in turns. Absence of palpable abnormalities and clinical signs incriminating other areas of pain in the hindlimb, particularly in a racehorse, would make me consider the MTP joint region, because it is the most commonly overlooked area in my practice. In horses with bilateral MTP joint lameness, poor performance may be the only historical finding and overt signs of lameness may not be present, but a short, choppy gait or intermittent, shifting hindlimb lameness is seen. A

gait typical of bilateral stress-related bone injury of the distal aspect of the MtIII in TB racehorses being trotted in hand is described as an “exaggerated pelvic excursion” in a dorsoventral direction (see Chapter 107).

Clinical signs of MTP joint lameness vary from subtle to overt and depend on the nature and severity of injury. Signs of inflammation may be absent in horses with stress-related bone injury but severe in horses with displaced or comminuted fractures. At the trot limb flight is similar to lameness originating from the metatarsal region and hock. As the limb moves forward, it deviates medially and is then stabbed laterally at the end of the cranial phase of the stride. The cranial phase is shortened commensurately with the degree of pain. Lameness is more pronounced with the affected limb on the inside of a circle. I find it useful to characterize clinical signs into three categories: severe, unrelenting lameness; intermittent, severe lameness; and chronic, low-grade lameness. TB racehorses often have bilateral MTP joint pain and show poor hindlimb action and a tendency to bunny-hop behind in canter.

Severe, Unrelenting Lameness

The severe, unrelenting form of MTP joint lameness is associated with intraarticular fractures or severe, end-stage OA. Horses are obviously lame at the walk, cannot be trotted, and may be non-weight bearing. Deformity of the MTP joint may be obvious, as in horses with comminuted fractures of the proximal phalanx. Effusion is obvious and diffuse; periarticular soft tissue swelling may be present. Horses with acute, displaced condylar fractures of the MtIII may have acute, progressive edema of the diaphyseal region, and those with comminuted fractures of the proximal phalanx often have severe soft tissue swelling. Palpation and flexion elicit severe pain and, in horses with comminuted or displaced fractures, crepitus. Radiographs are usually diagnostic. This category includes severe, complete, or comminuted fractures (e.g., spiral fractures of the MtIII); comminuted or complete fractures of the proximal phalanx; midbody fractures of the PSBs; complex fractures involving the MtIII, the proximal phalanx, and the PSBs; luxation or subluxation; and end-stage OA. Horses with acute tendonitis of the deep digital flexor tendon (DDFT) with tenosynovitis can be severely lame, and intrathecal analgesia of the digital flexor tendon sheath (DFTS) may only partially remove pain. Ultrasonographic examination is required. However, some sports horses with DDFT lesions show lameness that is challenging to diagnose because of its sporadic nature.

Intermittent, Severe Lameness

Horses with intermittent, severe lameness of the MTP joint may be able to train and perform at some level but develop severe lameness afterward. When exhibiting clinical signs, horses are lame at the walk, even toe-touching lame, and are obviously lame at the trot (grade 3 or 4 of 5), but after resting and receiving nonsteroidal antiinflammatory drugs (NSAIDs), horses are often able to gallop, jog, or train within 1 to 5 days. In some instances horses may be able to race, only to become lame once again. When walking in hand, horses often show marked lameness while turning, even if they are sound while walking in a straight line. Obvious signs of inflammation usually are not present, but horses generally respond positively to the lower limb

flexion test and may show a painful response to deep palpation. Horses with incomplete midsagittal or dorsal (frontal) fractures of the proximal phalanx often manifest a painful response when firm digital pressure is placed on the proximal, dorsal aspect (see Figure 6-37). Effusion may be present, but it is often absent or minimal even in horses with incomplete fractures. Because clinical signs may be difficult to detect, diagnostic analgesia is often necessary. Radiographs are usually diagnostic, but if findings are equivocal or the radiographs are obtained before radiological changes develop, scintigraphic examination or follow-up radiographic examination in 10 to 14 days is required. Digital and computed radiography can be helpful. Conditions such as incomplete fractures of the MtIII, the proximal phalanx, and the PSBs and moderate OA are in this category.

Chronic, Low-Grade Lameness

Diagnosis of chronic, low-grade MTP joint lameness is difficult. Specific signs that localize lameness to the MTP joint are lacking, and lameness may be only subtle to mild (grade 1 of 5) at the trot in hand. Horses examined at the track and carrying a rider may show only mild lameness. In racehorses, effusion and the response to lower limb flexion varies, but it can be negative. There is often mild increase in temperature, a subtle but useful sign of subchondral bone injury. In nonracehorses there may be effusion of the MTP joint and often the DFTS, but effusion is often longstanding and may be easily overlooked if reported by the handler as preexistent. Palpation may reveal mildly suspicious areas (e.g., pain over the abaxial aspect of the PSBs) in horses with sesamoiditis, but in most horses no abnormalities are noted. Concomitant lameness of the MTP joint and stifle region, called *intra limb compensatory lameness*, occurs most often in racehorses but is recognized in nonracehorses, and clinical signs may not abate until both sites are blocked or treated. The association between the stifle and MTP joint is difficult to explain. In young horses with “loose stifles,” knuckling of the MTP joint occurs when horses, particularly STBs, are jogged or worked slowly. Perhaps stretching of MTP joint capsule attachments or early subchondral bone trauma occurs during knuckling. Horses with “loose stifles” are thought to have patellar ligament and muscular instability and laxity and may benefit from counterirritant injection and simultaneous management of the MTP joint problem.

Diagnostic analgesia is required to localize pain causing lameness to the MTP joint, but in many horses lameness is difficult to accurately assess with the horse at a trot in hand. It is extremely important to recognize the need to employ perineural diagnostic analgesic techniques in addition to or in lieu of intraarticular analgesia in order to abolish all pain associated with the MTP joint. Radiological findings may be normal and horses are referred for scintigraphic examination, which often reveals stress-related bone injury. Special radiographic images may be needed to evaluate the distal aspect of the MtIII or for accurate identification of osteochondral fragments located in the dorsal and plantar aspects of the joint. In this category are conditions such as stress-related bone injury of the MtIII, early OA, osteochondral fragments that occur traumatically or as the result of osteochondrosis, and sesamoiditis.

Diagnostic Analgesia

Articular pain originating from the MTP joint can usually be abolished or at least partially alleviated by intraarticular analgesia. Because only one injection is required, intraarticular analgesia is easier and safer to perform than perineural techniques, but pain originating from subchondral bone may not abate or may be only partially alleviated by intraarticular analgesia. Therefore, it is extremely important to recognize that *the low plantar perineural technique or a variation must be used, because it is more effective in alleviating pain from all sources* (see Chapter 10).

A variation of the low plantar block, the lateral plantar metatarsal block, can be performed in horses with stress-related bone injury of the distal plantarolateral aspect of the MtIII (see Chapter 107).⁵ This block is particularly valuable in horses with bilateral lameness, because after one limb is blocked, the horse becomes obviously lame in the other. Other sources of pain located laterally in the MTP joint, such as sesamoiditis, small fractures of the PSBs, can be blocked by this technique, but the most common reason horses improve after lateral plantar metatarsal analgesia is alleviation of subchondral bone pain of the distal aspect of the MtIII.

In horses with chronic, low-grade lameness it may be necessary to perform analgesia and watch the horse train. Resolution of subtle signs, such as bearing in or out, not feeling right behind, performing dressage maneuvers, or, in STB racehorses, being on a shaft or a line, may be the only sign of a positive response to diagnostic analgesia. Although perineural analgesia may result in slight loss of proprioception, it is generally preferable, because intraarticular analgesia may result in a false-negative response. If pain is elicited by firm palpation of the dorsoproximal aspect of the proximal phalanx, suspect a midsagittal fracture. Nerve blocks are contraindicated because of the risk of creating a complete or comminuted fracture.

The clinician should be aware that it is possible to inadvertently block pain associated with subchondral bone of the MTP joint when performing plantar digital or plantar perineural analgesia. This occurs most frequently in racehorses with midsagittal fracture of the proximal phalanx but can occur in horses with OA or other conditions (see Chapters 10 and 41).

IMAGING CONSIDERATIONS

Radiography and Radiology

Examination should include dorsoplantar (DPI), lateromedial (LM), dorsolateral-plantaromedial oblique (DL-PIMO), and dorsomedial-plantarolateral oblique (DM-PILO) images. A flexed LM image is useful to evaluate the sagittal ridge for the presence of osteochondrosis lesions and to see dorsal frontal fractures of the proximal phalanx. Vacuum phenomenon can occur because the MTP joint can be placed in extreme flexion. Sudden decompression of the joint during stress flexion is believed to cause what appears to be an air artifact in the distal plantar aspect of the MtIII.⁶

Horizontal oblique images are useful to evaluate the proximal-dorsal aspect of the proximal phalanx for the presence of osteochondral fragments, but overlap between the base of the PSBs and the proximal aspect of the proximal phalanx can hide lesions associated with the

Fig. 42-1 • **A**, Dorsal 45° lateral-plantaromedial oblique digital radiographic image of a 3-year-old Standardbred filly with maladaptive subchondral bone remodeling obtained using a horizontal x-ray beam. Often, there is overlap between the base of the proximal sesamoid bones (PSBs) and proximal aspect of the proximal phalanx (*white arrow*), but in this well-positioned view no overlap exists. A medial, plantar osteochondral fragment can be seen (*black arrow*). **B**, Dorsal 20° proximal, 45° lateral-plantarodistal medial oblique digital radiographic image of the same filly showing a large radiolucent lesion in the distal aspect of the lateral condyle of the third metatarsal bone (MtIII) that was not seen in a conventional oblique image (**A**). A proximodistal (down-angled) radiographic image opens up the space between the PSBs and the proximal phalanx. **C**, A similar down-angled oblique image of the plantaromedial aspect of the joint allows complete visibility of the plantar osteochondral fragment (*arrow*).

distal-plantar aspect of the joint. Overlap in the plantar aspect of this joint is more common than in the metacarpophalangeal joint and occurs when the distal hindlimb is not vertically positioned. The x-ray beam should be angled down 15 to 20 degrees to separate the PSBs and proximal phalanx (Figure 42-1).

Using a horizontal x-ray beam in a DPL image, the PSBs are superimposed over the distal aspect of the MtIII and the MTP joint. To better evaluate these areas, dorsal 15° proximal-plantarodistal oblique (D15° Pr-PIDiO), flexed DPL, and standing 125-degree DPL images should be used. Proximolateral (medial)-distolateral (medial) and proximoplantar-distoplantar tangential images of the PSBs are occasionally used to evaluate the abaxial and plantar surfaces of the PSBs, respectively.

Approximately 5% to 10% of normal horses have a small unilateral or bilateral radiolucent notch (<1 mm in length) in the sagittal groove of the proximal phalanx that is seen in a DPL image and should not be confused with a midsagittal fracture. I have seen this “notch” most commonly in the DPL image of the STB racehorse. If clinical signs are consistent with midsagittal fracture, scintigraphic examination is recommended. Flattening of the plantar distal aspect of the MtIII condyles is not as common as in the metacarpophalangeal joint, but increased radiopacity of the plantar aspect of the MtIII can be seen in horses with stress-related bone injury and early OA if well-exposed LM and flexed LM images are obtained. I question the clinical significance of flattening of the condyles of the MtIII in most horses. Digital and computed radiographs are useful in the evaluation of horses with stress-related bone injury and incomplete fractures. Computed tomography (CT) and magnetic resonance imaging (MRI; see later) are also useful, but availability is limited.

Scintigraphic Examination

Scintigraphic examination is the best way to establish a diagnosis in many horses with intermittent, severe, or chronic low-grade lameness of the MTP joint. The most common scintigraphic findings in the MTP joint of STB and TB racehorses are focal areas of increased radiopharmaceutical uptake (IRU) that involve the distal plantarolateral aspect of the MtIII (see Figure 19-20, A; Figures 42-2 and 42-3).⁷ This IRU is a form of stress-related bone injury and early OA that is found in many racehorses with chronic, low-grade lameness, bilateral hindlimb lameness, and poor performance. Special radiographic images may then reveal increased radiopacity or radiolucent defects (see Figures 42-1 and 42-3). Similar scintigraphic findings are seen in horses with lateral condylar fractures of the MtIII. Focal areas of IRU are seen in horses with midsagittal or dorsal frontal fractures of the proximal phalanx (see Figure 19-20, C), sesamoiditis (Figure 42-4), and osteochondrosis of the plantar process of the proximal phalanx (see Figure 23-1; Figure 42-5). Often areas of IRU are found in unusual sites, such as those associated with the medial PSB (osteochondral fragments of the abaxial border and sesamoiditis), intersesamoidean ligament injury with radiolucent defects in one or both PSBs, incomplete fractures of the PSBs, and medial condylar fractures of the MtIII. Any focal area of IRU located medially in the MTP joint should be investigated, because incidental findings are unusual in this location.

Scintigraphic changes are usually less pronounced in nonracehorses, and negative or equivocal results often occur. The most common scintigraphic findings in jumpers and dressage horses with MTP joint lameness are diffuse mild areas of IRU in all bones or focal mild or moderate IRU in the dorsal or central aspects of the joint that involve

Fig. 42-2 • A, Plantar (lateral to the left) and flexed lateral (on the right) left hindlimb and **B**, plantar (lateral to the right) and lateral (on the right) right hindlimb delayed (bone) phase scintigraphic images of the metatarsophalangeal (MTP) joint in two Standardbred racehorses. All images show focal increased radiopharmaceutical uptake of the distal, plantarolateral aspect of the third metatarsal bone, which is the most common scintigraphic finding in the MTP joint of racehorses.

the distal aspect of the MtIII and proximal aspect of the proximal phalanx and are associated with radiological evidence of marginal osteophytes and enthesophytes. There is a distinct difference in the scintigraphic and radiological appearance of the MTP joint of nonracehorses and racehorses, because in racehorses IRU is generally focal in nature and IRU and radiological changes involve the plantar aspect of the joint. In a 2004 study of clinically sound horses, generalized, even radiopharmaceutical uptake across the distal aspect of the MtIII and the proximal aspect of the proximal phalanx was found.⁸ Radiopharmaceutical uptake was significantly higher in the condyles of the MtIII of hindlimbs than in forelimbs, there was no effect of age, and there was a trend for region of interest ratios to be higher in the right hind MTP joint when compared with the left.⁸ In some nonracehorses arthroscopic examination has revealed full-thickness cartilage damage that primarily involves the distal dorsomedial aspect of the MtIII (medial condyle) and is consistent with OA. Focal IRU in the proximal aspect of the plantar pouch is seen in

Fig. 42-3 • A, Lateral (on the left) and plantar (lateral to the left) bone phase scintigraphic images of a metatarsophalangeal joint. There is increased radiopharmaceutical uptake in the plantar aspect of the lateral condyle of the third metatarsal bone. **B**, Dorsolateral proximal-plantaromedial distal oblique xeroradiographic image showing a radiolucent defect (arrow) of the same area. This defect can easily be missed on routinely positioned images, but the increased radiopharmaceutical uptake seen in this area scintigraphically (**A**) prompted further investigation.

horses with severe OA (an ominous finding) (see Figure 19-20, *B*). I believe this finding is caused by accumulation of subchondral bone fragments in this location or modeling of the distal plantar aspect of the MtIII.

Magnetic Resonance Imaging

MRI is useful to evaluate bone and soft tissue abnormalities in the MTP joint and nearby structures (see Chapters 21, 107, and 108). In fact, in some horse-dense locations such as Newmarket, England, examination of the metacarpophalangeal and MTP joints using standing low-field MRI has become as commonplace as scintigraphic examination and is often preferentially requested by TB trainers.⁹ In TB and STB racehorses with maladaptive or nonadaptive bone remodeling of the distal aspect of the MtIII, MRI

Fig. 42-4 • Flexed lateral delayed (bone) phase scintigraphic image of a 2-year-old Standardbred racehorse with lateral sesamoiditis. There is focal moderate increased radiopharmaceutical uptake in the proximal sesamoid bones (arrow). When these findings were combined with those of the plantar image, the increased radiopharmaceutical uptake was localized to the lateral proximal sesamoid bone.

examination reveals extensive subchondral bone damage characterized predominately by low signal intensity of the plantar aspect of the lateral condyle of MtIII on T1- and T2-weighted images, a finding supporting the existence of chronic, sclerotic subchondral bone (Figure 42-6, A and B). Within the areas of low signal intensity is often a small area of high signal intensity near the articular cartilage (see Figure 42-6, A and B). In fat-suppressed short tau inversion recovery (STIR) image sequences, small, focal areas of high signal intensity within sclerotic bone are often found, indicating the presence of necrotic, and perhaps ischemic, bone, but widespread areas of high signal intensity consistent with bone edema from acute trauma are not often seen (Figure 42-6, C). Although numerous authors or speakers have characterized these lesions as bone bruises, bone edema (fluid accumulation) characteristic of bone bruises found in subchondral bone in people is not a hallmark of this common lesion in horses. Large areas of increased signal intensity likely indicated the presence of a fracture of the MtIII. Areas of increased signal intensity within sclerotic subchondral bone in horses with repetitive stress injuries could represent proteinaceous fluid, but likely represent regions of necrotic bone or granulation tissue.⁹ Areas of necrotic bone seen on magnetic resonance (MR) images correspond to radiolucent defects. Areas of bone loss, necrotic subchondral bone, or areas of intense resorption within sclerotic bone may warrant consideration when trying to manage horses with this lesion (see later). In horses with acute-onset clinical signs consistent with acute subchondral bone injury or fracture, bone edema can be more prominent. In 13 horses, most of which were non-racehorses, with lameness of metacarpophalangeal or MTP joints and without radiological abnormalities, the most common finding was decreased signal intensity in T1-weighted images, indicating the presence of sclerotic subchondral bone.¹⁰ In nine horses, decreased signal intensity

in T2*-weighted images was consistent with sclerosis, but five had increased signal intensity in fat-suppressed STIR images consistent with what was described as fluid accumulation within the sclerotic regions.¹⁰ Importantly, MRI abnormalities and subchondral bone lesions were found not only in racehorses but in horses used for show jumping and general purpose riding.¹⁰ Lesions similar to those described for racehorses were seen in the MTP joint of sports horses.¹¹ Focal areas of IRU seen scintigraphically appeared in MR images as areas of low signal intensity on T1- and T2-weighted images with or without small areas of increased signal intensity in STIR images, indicating the presence of chronic, repetitive stress injuries of the distal aspect of the MtIII in sports horses in addition to acute, traumatic injuries.¹¹ In an earlier study of 11 horses (eight racehorses), subchondral bone damage was identified using MRI, although there were no or equivocal radiological abnormalities.¹² Four horses had lesions in the metacarpophalangeal or MTP joints. Horses with acute-onset lameness had subchondral bone injury characterized by increased signal intensity in STIR and T2-weighted images.¹² In two horses, decreased signal intensity in proton density images (similar to T1-weighted images) indicated the presence of sclerotic subchondral bone of the distal aspect of the MtIII, but dense bone was surrounded by areas of increased signal intensity in STIR sequences.¹² Only two horses had bone scintigraphy performed, and areas of IRU in the damaged subchondral bone were seen.¹² Horses with acute subchondral bone injury should improve with rest, whereas those with chronic, sclerotic, and osteoarthritic subchondral bone may improve temporarily with rest but long-term prognosis is guarded. MRI was useful in the evaluation of horses with oblique and straight distal sesamoidean desmitis in 27 horses with lameness localized to the metacarpophalangeal or MTP joint region, of which 17 had lameness and injury in the hindlimb.¹³ Careful examination of soft tissue structures associated with the MTP joint, including use of diagnostic ultrasonographic examination, is necessary, because in some horses the results of diagnostic analgesia will be ineffective at differentiating authentic sources of pain in the region.

Ultrasonographic Examination

Ultrasonographic examination of the MTP joint region is indicated for suspensory branch desmitis (see Chapter 72). The abaxial aspect of the PSBs should be examined carefully to identify tearing and small avulsion fractures. Proliferative synovitis (villonodular synovitis) is unusual in the MTP joint. The DDFT should be evaluated carefully if tenosynovitis of the DFTS is present¹⁴ (see Chapter 74). Ultrasonographic examination is useful in horses with intersesamoidean and collateral ligament injuries or those with wounds and draining tracts to look for foreign material or communication with the articular surface. The distal sesamoidean ligaments should also be examined carefully, because intraarticular analgesia of the MTP joint has the potential to resolve lameness associated with injury to these ligaments, which can be present with no localizing clinical signs.

Computed Tomography

CT (see Chapter 20) is useful to characterize complex fractures of the MTP joint, to aid in preoperative planning for

Fig. 42-5 • A, Plantar (left, lateral is to the right) and flexed lateral delayed (bone) phase scintigraphic images of a 3-year-old Standardbred trotter. There is focal mild increased radiopharmaceutical uptake (IRU) involving the proximal aspect of the proximal phalanx (*arrows*), evidence of mild bone modeling associated with lateral and medial axial articular osteochondral fragments of the plantar process of the proximal phalanx. IRU of the lateral aspect of the distal phalanx in the hindlimb is a common incidental scintigraphic finding. **B,** Dorsal 20° proximal lateral-plantarodistal medial oblique digital radiographic image of the same horse showing the presence of lateral (*white arrow*) and medial (*black arrow*) articular osteochondral fragments. Osteochondrosis lesions occur in this region more commonly on the medial aspect of the proximal phalanx but can be biaxial. **C,** Intraoperative arthroscopic photograph (plantar is to the left and proximal is uppermost) showing the medial fragment interposed between the base of the medial proximal sesamoid bone (PSB) and the proximal phalanx. The medial condyle of the third metatarsal bone (MtIII) is immediately dorsal to the fragment. The arthroscope was positioned in the lateral plantar pouch, and separate instrument incisions were used to remove both the medial (shown) and lateral fragments.

surgical repair, and to study other defects of articular surfaces. CT has been found to be superior to radiology in detecting articular comminution, small cracks and lucencies in the MtIII condyles, and fractures of the PSBs.¹⁵ However, orthogonal radiography has been found to be superior to CT in detecting fractures of the dorsal aspect of the proximal phalanx, and both imaging modalities were poor at detecting plantar fractures of the proximal phalanx and coalescing cracks in the subchondral bone of the MtIII.¹⁵

CT is not as useful as scintigraphy and MRI in the evaluation of subchondral bone injury.

Arthroscopic Examination

Arthroscopic surgery is used frequently for removal of osteochondral fragments and fractures of the PSBs, assistance in fracture reduction and screw placement in horses with condylar fractures of the distal aspect of the MtIII and fractures of the proximal phalanx, and lavage and

Fig. 42-6 • Sagittal, low-field (0.25T) magnetic resonance images, obtained with the horse under general anesthesia, of a 4-year-old Thoroughbred racehorse with lameness localized to the lateral aspect of the right metatarsophalangeal joint by using lateral plantar metatarsal analgesia. **A**, T1-weighted image showing decreased signal intensity (arrows) surrounding an area of increased signal intensity (arrowheads). **B**, T2-weighted image showing the same signal distribution, indicating there is dense, sclerotic subchondral bone surrounding an area of necrotic, ischemic subchondral bone or fluid accumulation. **C**, Short tau inversion recovery (STIR) image showing increased signal intensity (arrow), confirming the presence of an area of necrotic subchondral bone within dense, sclerotic bone typical of a horse with stress-related subchondral bone damage.

debridement in horses with infectious arthritis. Diagnostic arthroscopic examination is indicated if lameness is localized to the MTP joint but radiological findings are negative or suggestive of occult osteochondral fragments, but such examination should be undertaken after evaluating the results of advanced imaging such as scintigraphic imaging and MRI. Before I was able to routinely use scintigraphy I often elected to evaluate the articular surface of the MTP joint arthroscopically, only to be disappointed in my inability to substantiate obvious abnormalities. Using scintigraphy and more recently MRI, I can often characterize injury of the joint without the need for diagnostic arthroscopy. The most common diagnosis is subchondral bone injury without obvious overlying cartilage damage, findings that obviate the need to examine the joint arthroscopically.

Diagnostic arthroscopy is indicated if cartilage damage or osteochondral fragments are suspected, and to confirm the extent of cartilage damage in horses with OA. Occult fragments involving the proximodorsal aspect of the proximal phalanx are occasionally found. Cartilage damage, sometimes full thickness, is found on the distal-dorsal aspect of the MtIII and the proximal aspect of the proximal phalanx in nonracehorses. In racehorses with OA, cartilage lesions are usually most pronounced in the plantar pouch, with extensive scoring or large areas of full-thickness damage and exposed subchondral bone on the PSBs. Although stress-related bone injury and later overlying cartilage damage is seen on the distal plantarolateral aspect of the MtIII, this area is difficult to evaluate during arthroscopic examination (Figure 42-7).

Fig. 42-7 • Intraoperative photograph of a 5-year-old Standardbred trotter with severe stress-related bone injury of the distal plantarolateral aspect of the third metatarsal bone (arrows). This area was debrided and the horse raced, but it dropped substantially in race class and was retired.

SPECIFIC CONDITIONS OF THE METATARSOPHALANGEAL JOINT

Stress-Related Subchondral Bone Injury and Osteoarthritis

The term OA implies disease of both the supporting bone and the articular surface of the MTP joint. The concept that the earliest lesion in OA of the MTP joint in racehorses begins in subchondral bone is essential to understanding clinical signs, successful use of diagnostic analgesia, progression of bone and cartilage loss, and the horse's response (or lack thereof) to therapy. There are two syndromes of MTP joint OA; one is seen in racehorses and the other in nonracehorse sports horses.

In racehorses, OA begins as a maladaptive or nonadaptive stress-related bone injury in subchondral bone. Subchondral maladaptive or nonadaptive bone injury is the most common reason I examine TB and STB racehorses with hindlimb lameness or poor performance. Although the overlying cartilage may be biomechanically and biochemically inferior, obvious clinical signs such as synovitis and a positive response to lower limb flexion are not seen until later. Low-grade unilateral or bilateral lameness is present, which is localized best by low plantar or lateral plantar metatarsal analgesia. Often, horses have a short, choppy gait, mimicking what would be expected if horses had bilateral or, in some, quadrilateral foot pain. Most often, blocking one hindlimb produces obvious contralateral hindlimb lameness in horses with bilateral subchondral bone injury. Horses are often thought to have something "up high" and usually have been unsuccessfully treated for other suspected sources of hindlimb pain. Early stress-related bone injury is best substantiated using scintigraphic examination. Focal areas of IRU are present in the MtIII; the PSBs and the proximal aspect of the proximal phalanx also can be affected (see Figures 19-20, 42-2, and 42-3). Initial radiological findings either are negative or reveal subtle increased radiopacity, but later radiolucent defects develop in subchondral bone, which are best revealed in a DPrL-PIDiMO image (see Figure 42-3). Increased radiopacity is most obvious in the LM, flexed LM, and DPrL-PIDiMO images.

Fig. 42-8 • Dorsal plane microradiograph (100 μ m) of the distal aspect of the third metatarsal bone (lateral is to the right) showing dense subchondral sclerosis and an area of intense resorption or necrosis of bone (arrow). Cartilage overlying this area is intact. Severe subchondral modeling and remodeling and later osteoarthritis develop in the metatarsophalangeal joints of racehorses.

Later, overlying full-thickness cartilage damage develops (see Figures 19-20, B, 23-8, and 42-7; Figure 42-8). Stress-related bone injury can continue to the point where severe OA or fracture of the MtIII develops; this type of severe injury is most common in racehorses 4 to 6 years old (see Figures 19-20 and 23-8). However, in some STBs the process causes lameness when horses are 2- or early 3-year-olds and then subsides or stabilizes. The condition is rarely seen in STBs until training speeds faster than 2 minutes, 20 seconds for a mile are achieved. In TB racehorses, this remodeling process is common in later 2- and 3-year-olds but can also be seen in older horses. Older horses given time off because of undiagnosed lameness or other conditions are at risk to develop stress-related bone injury in the MTP joint 6 to 8 weeks after returning to training, when signs of poor gait or lameness develop and a focal area of IRU can be identified. In my experience, subchondral lucency occurs later in the TB than in the STB and is uncommon. Differences between the racing breeds related to gait, speed, and load distribution may account for this difference in progression of OA. End-stage OA develops in STB racehorses that have continued racing for many years and can be progressive in broodmares and breeding stallions.

In nonracehorse sports horses OA is an insidious process usually without marked subchondral bone involvement. Bone and cartilage gradually deteriorate. Some horses affected may be ex-racehorses, but most are not. I have observed OA of the MTP joint mostly in upper-level jumpers and dressage horses. In these horses lameness is often chronic and low grade (grade 1 or 2 of 5), but it can progress to severe or intermittently severe. Effusion and a positive response to lower limb flexion are common findings. Concomitant tenosynovitis of the DFTS and previous lameness caused by suspensory desmitis and distal hock joint pain are common. Lameness is more consistently abolished using intraarticular analgesia in jumpers and dressage horses than in racehorses, but in some horses low plantar analgesia is required. Marginal osteophytes and enthesophytes are often detectable radiologically. Scintigraphy may reveal focal IRU in the central or dorsal aspect of the joint, diffuse IRU, or equivocal findings, and scintigraphic abnormalities are usually much less obvious than those

found in racehorses. Occasionally, acute-onset lameness associated with focal IRU of the distal aspect of the MtIII occurs that is similar to that found in racehorses. This lameness may indicate acute subchondral overload trauma from landing wrong after jumping a fence, stepping on uneven ground, or sustaining a fall or other accident in a paddock. In nonracehorse sports horses, arthroscopic examination often reveals cartilage damage most extensive in the dorsal aspect of the joint, marginal osteophytes on the apices of the PSBs, and occasionally osteochondral fragments of the proximal dorsal aspect of the proximal phalanx.

Shoeing and hoof balance may play a role in development or expression of clinical signs of OA in all horses but may be more important in racehorses. In the STB racehorse clinical signs often develop within 2 to 3 weeks of a shoeing change, usually with the application of aluminum shoes with a low toe grab. Aluminum shoes are light and generally applied to pacers that are close to qualifying speed, but they are often used in trotters as well. Shear stress associated with these shoes may exacerbate existing disease or cause further trauma to subchondral bone. Aluminum shoeing is common in TB racehorses in North America, where these shoes are associated with other fetlock joint lameness and catastrophic breakdown. An aluminum shoe with a toe grab and with turned-down heels has been commonly used in recent years, and I have observed this shoe in many TBs with subchondral bone injury of the distal aspect of the MtIII, severe suspensory branch desmitis, and other catastrophic injuries of the MTP joint. Abnormal hoof wear caused by gait, the presence of concomitant distal hock joint or metatarsal region pain, or hoof imbalance may cause asymmetrical loading of the MTP joint and add to subchondral bone trauma.

Management of Stress-Related Bone Injury and Osteoarthritis

Reducing bone stress is key to initial management in racehorses with early OA characterized primarily by stress-related bone injury, because high-impact loading or high-strain cyclic fatigue of subchondral bone is the primary lesion. In STBs I previously recommended 4 to 6 weeks of light jogging (<2 miles per day), but results were poor even if recommendations were followed. I reassessed several horses after 6 weeks of light jogging, and although scintigraphic changes subsided, the horses were still as lame or slightly worse. I now recommend 3 weeks of walking and light jogging followed by reevaluation. Although 3 weeks' reduction in training may allow early healing or remodeling of damaged subchondral bone and microfractures, bone and muscle undergo detraining and horses need several (i.e., 3 to 6) weeks of slow return to normal exercise intensity. If lameness resolves, horses are returned to training, but if lameness persists I recommend 3 to 4 months of rest. In TBs, recurrence is quite high if horses are given only 6 to 8 weeks of rest. I recommend either 3 to 4 months of turnout or a program of 3 weeks of handwalking, followed by 3 weeks of walking with a rider up, followed by 3 weeks of trotting either with a rider up or using an exercise pony. Longer periods of rest would likely be beneficial to allow complete healing of subchondral bone, but most often owners and trainers are reluctant to agree. A gradual return to normal exercise intensity is then recommended if horses are sound and moving well.

Hoof balance and shoeing characteristics should be evaluated and in most instances changed. A simple change in shoeing to an easier shoe, such as a flat steel or aluminum shoe, may reduce shear and torsion of the MTP joint. Toe grabs and any other shoe additives must be removed. Perhaps the best change, if possible, is to leave the horse barefoot for several weeks. If medial-to-lateral hoof imbalance is poor, it should be corrected. The relationship of track and training surface to the development of subchondral bone injury is currently unknown, but this type of injury is quite common in TB racehorses training and racing in Europe and other countries, in which grass and all-weather (synthetic) surfaces are used (see Chapter 107). Although incidence of race-day injuries may change from a change in track surface, it is the track surface on which the horse trains, and thus the surface that cancellous and cortical bone "sees" day to day, that likely influences bone modeling and remodeling. In an unpublished preliminary study, we found that areas of IRU of the distal aspect of the MtIII or the third metacarpal bone (McIII) were the most common scintigraphic abnormality in horses training on grass and a synthetic surface, and although MTP or metacarpophalangeal lameness was common, the prevalence of stress fractures of long bones was markedly reduced compared with a cohort of TB racehorses training on dirt.¹⁶ These results differ from anecdotal reports of injuries being discovered in TB racehorses being trained and raced on synthetic surfaces. Sporadic or clustering of injuries appears common, ranging from numerous horses developing unusual muscle injuries in the upper hindlimbs to an overabundance of stress fractures. Stress-related subchondral bone injury has been a predominant finding by some practitioners evaluating horses training on synthetic surfaces but not by all. In some racing jurisdictions, high toe grabs and turned-down shoes cannot be worn by horses racing on synthetic surfaces, a fact that may complicate epidemiological studies of injuries because this type of shoeing has been linked to substantial and sometimes fatal injuries of the metacarpophalangeal or MTP joints. In my opinion a change of shoeing philosophy to flat racing plates and, from the therapeutic standpoint, training horses without hind shoes may reduce negative forces acting on the MTP joint.

Because the initial lesion is in subchondral bone, intraarticular injections appear to have limited therapeutic benefit but may make theoretical sense. Active treatment may help in persuading trainers to follow the recommended work program. A series of three intraarticular injections of polysulfated glycosaminoglycans (PSGAGs) are given every other week. Alternatively, if horses are currently racing but have mild unilateral or bilateral lameness or scintigraphic evidence of stress-related bone injury and poor performance, I recommend intraarticular injection with hyaluronan and methylprednisolone acetate (80 mg). Intramuscular administration of PSGAGs (once weekly for 8 weeks) is recommended, but therapeutic benefit is difficult to assess. NSAIDs such as phenylbutazone (2.2 to 4.4 mg/kg bid) are recommended. NSAIDs may help horses in modified exercise programs "get over the hump" when lameness persists after scintigraphic evidence of stress-related bone injury subsides. Because pathogenesis involves sclerotic subchondral bone, the roles of ischemia and increased intraosseous pressure in causing bone pain or

necrosis and subsequent collapse of weakened areas of subchondral bone have been questioned. I used to recommend the administration of isoxsuprine (400 mg bid orally) in an attempt to improve peripheral blood flow. However, research evidence supports neither the achievement of adequate blood levels nor increased blood flow by use of the drug, and I do not currently recommend its use. Other drugs, such as aspirin (17 mg/kg bid orally), may be useful in improving blood flow, but half-life is short and therapeutic benefit has yet to be established. If increased intraosseous pressure and early ischemia lead to pain and subchondral bone damage, a procedure such as subchondral bone drilling, which is used to manage stress-related bone injury in cortical bone of the McIII, may be beneficial, but it is currently only experimental. Topical counterirritation has historically been used and makes theoretical sense in horses with stress-related bone injury if increased blood flow occurs. The time-honored treatment of blistering and turning out may be the best method of management. I have used focused shock-wave therapy in some STB and TB racehorses with stress-related bone injury by aiming the shock waves at the plantarolateral aspect of the MtIII. Early results appear promising, but horses are given concurrent modified exercise programs and other therapy.

Bisphosphonate Therapy for Management of Subchondral Bone Pain

The bisphosphonate drug tiludronate has received considerable attention in recent years for management of numerous lameness problems, but although there are many anecdotal reports there is scant scientific evidence to support its use in the horse. Bisphosphonate drugs are largely antiresorptive and work by reducing osteoclastic activity. In maladaptive or nonadaptive bone remodeling and in horses with more advanced OA the predominant process is one of bone accumulation; dense sclerotic bone develops in the subchondral plate and adjacent cancellous bone, so in theory a drug to reduce osteoclastic resorption might have a net effect of *increasing* bone formation. How and why would antiresorptive drugs work in predominantly sclerotic subchondral bone? Bisphosphonate compounds may help to normalize metabolism in bone injuries characterized by abnormal resorption and formation, such as what is seen with navicular disease, a disease with similarities to maladaptive or nonadaptive remodeling of the MtIII and other bones. Based on this theory, in a double-blind, placebo-controlled study, there was improvement in lameness scores of horses with navicular disease given tiludronate at 1 mg/kg intravenously (IV) once daily for 10 days and horses returned to a normal level of activity 2 to 6 months after administration.¹⁷ Furthermore, horses with OA of the thoracolumbar vertebral column given the same dose of tiludronate showed significant improvement in dorsal flexibility compared with untreated controls.¹⁸ In horses, adaptive response to high-strain cyclic fatigue in the subchondral plate and adjacent subchondral bone occurs in response to race training. In a histological study of TB distal MtIII and McIII condyles, site-specific increases in microcrack density in calcified cartilage and resorption spaces in the adjacent subchondral plate were interpreted as evidence of mechanical failure of the joint surface from progressive endochondral ossification and modeling or remodeling of subchondral bone.¹⁹ Propagation of

microcracks into subchondral bone may be critical to the subsequent development of condylar fractures or OA.¹⁹ In sclerotic subchondral bone, osteocyte morphology was abnormal and numbers were reduced, but site-specific microdamage, targeted remodeling of adjacent subchondral bone, and multiple pathways of mechanotransduction of the McIII were thought to be important in adaptation to exercise.²⁰ In a study of 25 distal McIII condyles of TB racehorses, extensive microcrack formation leading to microfracture was found in sclerotic subchondral bone close to the calcified cartilage layer, and the presence of osteoclastic resorption along microfracture lines was proposed to have caused previous weakening.²¹ In these studies the presence of resorption and bone weakening in calcified cartilage and adjacent subchondral bone may lend evidence to justify the use of bisphosphonate compounds, primarily for reduction in resorption and potentiation of healing of microdamage. In people with OA of the knee, joint space narrowing and sclerosis of the nearby subchondral plate occurs, and sclerotic bone may act to stress-protect adjacent cancellous bone, called *subarticular bone*, because vertical and horizontal trabeculae number were reduced, resulting in bone loss.²² Through use of fractal signature analysis to measure differences of cancellous bone density in osteoarthritic medial knee compartments in people, increased trabecular number associated with thinning and fenestration of trabeculae in subarticular regions confirmed that overall, cancellous bone was osteoporotic.²³ Osteoporosis, although not known to be found in horses with OA, could potentially be managed using bisphosphonate therapy. Bisphosphonate therapy alone²⁴ and in combination with estrogen therapy²⁵ slowed early changes in subchondral bone architecture and reduced the prevalence of osteoarthrosis-related subchondral bone lesions. Given the presence of intense resorption at various sites and the presence of osteoporotic subchondral bone, a case could be made for the administration of bisphosphonate drugs. Long-term studies and more double-blind, placebo-controlled studies¹⁷ need to be done.

Anecdotally, there may be benefit from use of tiludronate in horses with OA and subchondral bone injury, but it makes most sense to combine the drug with rest or a modification in exercise to allow healing of microdamage. Although lameness scores improved in horses with navicular disease,¹⁷ my limited experience in horses with subchondral bone pain of the distal aspect of the MtIII suggests that amelioration of lameness is subtle and that long-term evidence of benefit cannot be established. The drug can be used IV, at a dose of 1 mg/kg in a single infusion or divided over 10 days for a total dose of 1 mg/kg, because both dosage regimens resulted in similar plasma exposure and pharmacologic effects.²⁶ There has been a trend to administer the drug to horses with single distal limb lesions using intravenous regional limb perfusion techniques, but this technique would be impractical in horses with numerous abnormalities involving more than a single limb and has not been studied. Use of the drug and continued training and racing may potentially lead to condylar fracture or other further injury, particularly in TB racehorses, a sequela that should be strongly considered. Anecdotal reports suggest that there may be immediate improvement in lameness scores after bisphosphonate administration, indicating that an analgesic effect may occur that could

potentially lead to further training and racing. Currently I believe that targeting areas of bone resorption or necrosis and attempting to normalize subchondral bone formation and healing using bisphosphonate therapy in combination with a reduction in exercise intensity comprise a reasonable approach, particularly in horses with bilateral hindlimb subchondral bone pain (or more numerous abnormalities). I prefer a single slow, IV infusion (1 mg/kg) while warning owners and trainers about the limited collective knowledge of complications in the horse, such as signs of colic during or immediately after drug administration, and of the known complication of osteonecrosis of the jaw associated with bisphosphonate use in people.²⁷

Surgical Management of Subchondral Bone Injury

I have used the surgical technique of subchondral perforation (forage) in three horses—two TB and one STB racehorses—with unilateral hindlimb lameness in which lateral plantar metatarsal analgesia abolished lameness (horses did not show lameness in the contralateral hindlimb after blocking of the principal limb), and bone scintigraphy identified focal IRU of the distal, plantarolateral aspect of the MtIII. In one horse (Figure 42-9) MRI showed typical subchondral bone injury of the lateral MtIII condyle (see Figure 42-6). Arthroscopic examination of the plantar aspect of the MTP joint in all horses revealed normal-appearing articular cartilage, and by means of a combination of needles preplaced along the plantar aspect of the

Fig. 42-9 • **A**, Lateral (dorsal is to the left), plantar (lateral is to the left), and flexed lateral delayed-phase scintigraphic images of an unraced, 2-year-old pacing colt with left hindlimb lameness abolished with lateral plantar analgesia. Focal, moderate increased radiopharmaceutical uptake (IRU; arrows) of the distal, plantarolateral aspect of the third metatarsal bone (MtIII) is diagnostic for maladaptive or nonadaptive subchondral bone injury. **B**, Dorsal 20° proximal, 45° lateral-plantarodistal medial digital radiographic image showing a small radiolucent defect in the plantar aspect of the lateral condyle of the MtIII (arrow). **C**, T2-weighted magnetic resonance image of the left metatarsophalangeal joint (lateral is to the right; dorsal is uppermost) showing dense, sclerotic subchondral bone (arrows) surrounding an area of increased signal intensity in the region in which the radiolucent defect can be seen. An area of necrotic subchondral bone is present. **D**, Dorsal 20° proximal, 45° lateral-plantarodistal medial digital radiographic image obtained after three 3.5-mm holes were drilled from the lateral aspect of the lateral condyle through the damaged subchondral bone. This horse raced successfully as a 3-year-old.

MtIII under arthroscopic guidance and intraoperative fluoroscopy, three 3.5-mm holes were drilled in a lateral-to-medial direction through the plantar aspect of the lateral MtIII condyle. Drill holes extended past the axis of the MtIII into but not through the medial condyle. Horses were given 4 months of rest before returning to training. The rationale for this approach is similar to what is done in horses with dorsal cortical fractures of the McIII, in which osteostixis is performed. Subchondral forage may allow marrow components from the medial condyle and adjacent lateral condyle to repopulate and heal damaged subchondral bone, and there may be immediate decompression of painful, sclerotic subchondral bone. All three horses raced after surgery, but in one TB lameness recurred after two race starts. An alternative surgical approach of inserting a positional or set cortex bone screw may make theoretical sense.

In racehorses with more advanced OA the therapeutic value of intraarticular injections becomes greater, because overlying cartilage damage and synovitis become prominent. However, horses generally drop substantially in race class and eventually are retired. In TB racehorses, intraarticular injections have little benefit in horses in training but may have limited value in horses actively racing. The disease process appears to be self-limiting in TBs, because horses with continued chronic, low-grade lameness are often retired before the disease process advances, or horses develop compensatory lameness in the forelimbs. Although a putative relationship exists between horses with maladaptive or nonadaptive remodeling and the subsequent development of condylar fractures, this is difficult to substantiate. In three TB racehorses that subsequently developed condylar fractures, a previous bone scan showed IRU of the distal aspect of the McIII but radiographs were negative, lending some clinical evidence of a cause-and-effect relationship. I have seen numerous racehorses, most of which were STBs, that developed extensive OA of the MTP joint after earlier diagnosis with maladaptive or nonadaptive bone remodeling. It is possible that lameness from subchondral bone pain in numerous limbs may limit exertion, power, or race speed and cause poor performance, but not fracture. In essence, horses may not race fast enough to develop fractures. STB racehorses often go off stride or develop compensatory lameness problems, in the same limb or other limbs, that may lead to poor performance rather than fracture. In the TB racehorse subchondral radiolucency is unusual in my experience, but others have recognized progression of OA and the development of changes similar to those seen in STBs (see Chapter 108). Why some horses are able to race with persistence of IRU, radiolucency, and sclerosis whereas others cannot is not easy to answer. Prognosis for both racing breeds appears to be guarded to fair at best. Of 19 STBs with lameness and IRU of the plantarolateral aspect of the MtIII, 18 raced, but only 13 remained at the same racing class or improved.⁷ When radiolucent areas become prominent, arthroscopic examination and debridement may be an option, but it is difficult to manipulate instruments in the distal plantar pouch because manipulation must be done with the joint in flexion (see Figure 42-8). It is impossible to reach these lesions using a dorsal approach, because they are located approximately 8 mm plantar to the middle of the condyle. In horses with end-stage OA (i.e., loss of joint space, tilting of the sagittal

ridge and groove, and severe proliferative and radiolucent changes), arthrodesis must be considered in broodmare or stallion prospects (see Figure 23-8). Humane destruction may be necessary.

Nonracehorses often respond favorably to intraarticular injections of PSGAGs, hyaluronan, and short-acting corticosteroids (e.g., triamcinolone acetate, isoflupredone acetate) or long-acting corticosteroids (e.g., methylprednisolone acetate). Exercise level is reduced for a period of 2 to 3 weeks, and horses are given NSAIDs. Topical therapy using cold water hosing, poulticing, and bandaging is recommended. When lameness persists and scintigraphic examination reveals focal IRU in the dorsal aspect of the joint, or in horses with chronic lameness, long-term rest is necessary. Arthroscopic examination in these horses reveals areas of partial- or full-thickness cartilage damage that can be managed by debridement and microfracture into subchondral bone. However, the therapeutic value of arthroscopy is limited. If osteophytes are removed, they generally reform. If surgery is combined with rest, horses usually become sound, but lameness often returns when competition resumes. Prognosis for horses performing at the previous level of competition is guarded to poor. Rehabilitation of upper-level performance horses is quite difficult, because most have at least one compensatory lameness problem in addition to primary OA of the MTP joint. Horses may be able to perform at a lower level of competition.

Plantar Process Osteochondral Fragments

Fragmentation of the proximal plantar processes of the proximal phalanx is a common finding in young STBs and Warmbloods but is also seen in TBs, Arabians, and Western performance horses. This condition has become more frequently recognized since presale and postsale radiography has become common.

There are four distinct manifestations of decreasing frequency: axial articular fragments; abaxial, nonarticular fragments; nonarticular fragments originating from the base of the PSBs; and true acute fractures. (I prefer an anatomical description rather than reference to different types.²⁸) The condition is much more common in the hindlimbs, except for nonarticular fragments from the base of the PSBs, which occur almost exclusively in forelimbs (see Chapter 36). Combinations of axial and abaxial fragments often occur. The condition can be unilateral or bilateral and can be biaxial (involving both sides of the same joint).

Axial Articular Fragments

Axial articular fragments are most important and are most often medial, but can be lateral, biaxial, and bilateral. Of 119 horses with axial articular fragments, 92% were STBs; 95% of fragments were in the hindlimbs, most commonly the medial aspect of the left hindlimb (44%).²⁹ The incidence of axial articular fragments in 1- and 2-year-old STBs ranges from 5.6% to 28.8% but in TBs has been estimated at 2%.³⁰ The etiology remains controversial, but because STBs and the hindlimbs are clearly predisposed and fragments are recognized at an early age, osteochondrosis is the most likely explanation. Heritability estimates of axial articular fragments in STBs using a nonlinear model were

0.21, and fragments were seen in 11.8% of foals.³¹ I feel it is implausible that a large number of STB foals develop traumatic fractures at this site, whereas other breeds do not. I believe hereditary factors are most important. A traumatic cause has been suggested in some studies, because portions of the fragments were irregular, were entrapped by mature fibrous tissue, and contained spicules of bone not covered by fibrocartilage, which gave the histological appearance of a fracture healed by fibrous union.^{30,32,33} Evidence of short distal sesamoidean ligament insertions was not found and fragments were old.³⁰ Unfortunately, axial articular fragments examined were taken from horses with a mean age of 3.4 years and after horses had trained and raced, rather than from weanlings and yearlings, so degeneration and remodeling of fragments could have occurred. With only capsular attachments, how do alleged avulsion fractures occur? Etiology is most important when dispute or arbitration ensues after horses have been sold at public auction (see Chapter 99).

Chronic low-grade, high-speed MTP joint lameness can occur. Horses often have a previous history of other ipsilateral hindlimb lameness, such as distal hock joint pain. Effusion and a positive response to lower limb flexion are lacking or inconsistent. Lameness is alleviated most consistently with low plantar analgesia, but differentiation from early stress-related bone injury and OA can be difficult without scintigraphic examination. Stress-related bone injury or other bony abnormalities, such as midsagittal fracture of the proximal phalanx and occasionally condylar fractures of the MtIII, are commonly found simultaneously with axial articular fragments. Many horses with axial articular fragments never develop lameness, and fragments are detected only on survey radiographs. If and how axial articular fragments cause lameness is not well understood. Axial articular fragments may vibrate at speed or become interposed in the joint surface during flexion, but synovitis does not play a role. These fragments may affect mechanics of the ipsilateral PSB or impinge on distal sesamoidean ligaments.²⁸ Nociceptive fibers have been found in soft tissue attachments, and stretching during full extension may cause pain.³⁰ In older horses, evidence of full-thickness cartilage damage on the MtIII and the PSBs suggests that axial articular fragments may contribute to the development of OA.

Radiological examination reveals one or more fragments seen best in down-angled oblique views (see Figure 23-1, 42-1, and 42-5). If surgery is considered, both limbs should be examined radiographically. Scintigraphic examination may reveal mild abnormal bone modeling, but IRU is more commonly seen in horses with abaxial, nonarticular fragments (see Figure 42-5).

Axial articular fragments should be removed using arthroscopic surgery. In recent years I have advised removal of fragments before horses begin training, because "down time" associated with arthroscopic surgery is less than if surgery is performed in the middle of a racing year. Subjectively it appears that horses that undergo surgery earlier have fewer problems with stress-related bone injury and OA. In breeds such as the TB and Warmblood, axial articular fragments may complicate sales and can be removed prophylactically. During arthroscopic surgery fragments are carefully trimmed free of capsular attachments with a specially designed intraarticular blade and are removed.³⁴

If arthroscopic surgery is performed before training begins, horses are given 7 days of stall rest, followed by 7 days of stall rest with handwalking, then 7 to 14 days of walking in the jog cart (STBs) or walking and light trotting with an exercise pony (TB). If lameness develops when horses are in advanced stages of training or are racing, I recommend at least 2 to 3 months of rest before training resumes. The prognosis is good for future soundness if the fragment(s) caused the lameness. In one study 63% of racehorses and 100% of nonracehorses had performance similar to preinjury levels after surgery, but the presence of cartilage damage or synovial proliferation was significantly associated with an adverse outcome.²⁸

Abaxial, Nonarticular Fragments

Abaxial, nonarticular fragments can be single or multiple and may occur in combination with axial articular fragments, either on the same side or the opposite side of the joint. Abaxial, nonarticular fragments usually are lateral and can be bilateral. Abaxial, nonarticular fragments can be large and involve the entire lateral, plantar process (see Figure 23-1), including a small articular portion, but most are nonarticular. These fragments resemble old fractures radiologically, but I believe they are manifestations of osteochondrosis.^{31,33} Fragments are often seen in weanlings or yearlings without clinical signs of lameness, and when seen in older horses, lameness is rarely acute. Abaxial, nonarticular fragments have been described as ununited proximoplantar tuberosities, and in some horses fragments identified at a young age subsequently reunited with the parent bone.³⁵ In my experience, union of abaxial, nonarticular fragments in older horses is rare but does occur.

Lameness is mild (grade 1 of 5 with the horse in hand), usually present at high speed, and worse around turns. Pain is abolished by low plantar analgesia. Palpation may reveal mild bony enlargement, but this enlargement is easily missed. Once horses are clipped, bony swelling is obvious. Response to lower limb flexion is inconsistent. Occasionally a weanling or yearling develops acute lameness with obvious soft tissue swelling that involves the fetlock joint. Radiographs reveal an old abaxial, nonarticular fragment, but generally lameness resolves quickly and is not related to the fragment.

Radiographs reveal one or more abaxial, nonarticular fragments, which are occasionally accompanied by axial articular fragments (see Figure 23-1). Fragments are old and rounded, and radiolucent changes of the parent plantar process of the proximal phalanx are common. A clear separation exists between the fragment and proximal phalanx that is filled by dense, fibrous tissue. Scintigraphic examination may reveal mild IRU.

Abaxial, nonarticular fragments may or may not cause lameness, and clear differentiation between sources of pain can be difficult. The decision of whether to perform surgery is often difficult, because often conventional surgery is required to remove these nonarticular pieces.³⁴ Although the procedure is tedious and best done by using a motorized synovial resector, large abaxial fragments can be removed arthroscopically (see Chapter 23 and Figure 23-1). After surgery horses are given 4 weeks of stall rest, followed by 4 weeks of stall rest with handwalking, then 4 to 8 weeks of turnout in a small paddock or light jogging or galloping.

Prognosis is excellent for future soundness, but among STB racehorses, pacers have a better prognosis than trotters. In yearlings with a combination of axial articular fragments and abaxial, nonarticular fragments, I usually recommend arthroscopic surgery to remove axial articular fragments and leave abaxial, nonarticular fragments in place unless clinical signs develop at a later date.

Although I strongly believe that axial articular fragments and abaxial, nonarticular fragments cause lameness and I recommend surgery both therapeutically and prophylactically, others question the clinical significance of these fragments. In a study evaluating radiological findings in STBs before beginning training and subsequent race performance, there was no significant association between the presence of axial articular fragments, abaxial, nonarticular fragments, and other forms of osteochondrosis and either race performance or racing longevity.³⁶

Nonarticular Fragments Originating from the Proximal Sesamoid Bones

Nonarticular fragments originating from the PSBs, the most unusual form of fragmentation, are discussed in conjunction with plantar process fragmentation of the proximal phalanx since radiological findings can be similar to those associated with articular or nonarticular plantar process fragments. Nonarticular fragments originating from the PSBs occur almost exclusively in the forelimb and are rare in the hindlimb. Horses with this form of fragmentation have high-speed lameness and clinical signs are similar to those seen with the other, more common forms of plantar/palmar fragmentation. Radiologically, nonarticular fragments originating from the PSBs are best seen in LM radiographic images, are intercalated in the distal sesamoidean ligaments, can be singular or numerous, and are located plantar/palmar to the articular surface of the PSBs, usually midway between the PSBs and the proximal aspect of the proximal phalanx. These fragments may result from osteochondrosis or from avulsion injury that occurred when horses were sucklings. Nonarticular fragments originating from the PSBs can be removed by using a ligament-separating approach with conventional surgical techniques or by using arthroscopic techniques; a motorized synovial resector is required to debride capsular and distal sesamoidean ligament attachments. Damage to the distal sesamoidean ligaments is unavoidable and I question the value of surgical removal of these fragments. Horses generally return to racing or training at a level similar to that achieved before surgery and high-speed lameness often recurs.

Acute Fractures of the Proximal Plantar Process

True fractures of the proximal plantar process of the proximal phalanx occur, usually are recognized after known or suspected trauma, but are rare. Acute lameness and soft tissue swelling are present. Radiology reveals an acute fracture with a narrow, well-defined fracture line. The margins of the fracture are not rounded, nor are there radiolucent changes in the proximal phalanx. Internal fixation and fiberglass cast application are recommended. Prognosis depends on duration of the fracture before repair and fracture size. OA is a potential complication.

Osteochondrosis of the Sagittal Ridge of the Third Metatarsal Bone

A discussion of osteochondrosis of the sagittal ridge of the MtIII is presented in Chapters 36 and 56.

Osteochondral Fragments of the Dorsoproximal Aspect of the Proximal Phalanx

Osteochondral fragments of the dorsoproximal aspect of the proximal phalanx are common and occur in two forms. Well-rounded osteochondral fragments often occur in young horses, may be a manifestation of osteochondrosis, and are asymptomatic (Figure 42-10). In a recent study of 117 Warmblood horses with fragments in this location, histopathological examination of fragments removed arthroscopically revealed smooth hyaline cartilage surrounding a bony center, and fragments were thought to be a component of developmental orthopedic disease.³⁷ Acute osteochondral fragments result in mild lameness or change in performance and are associated with an effusion and a positive response to lower limb flexion (see Figure 23-6). Arthroscopic surgery and removal of these osteochondral fragments is recommended. In older STB and TB racehorses, osteochondral fragments can be large and numerous, and after surgery a minimum of 8 weeks' rest is given. Cartilage damage on the opposing surface of the MtIII is common, and the amount is commensurate with size and duration of osteochondral fragments.

Other Osteochondral Fragments

Osteochondral fragments may be identified dorsal or plantar to the collateral ligaments, usually laterally. These osteochondral fragments are usually traumatically induced and may originate from the distal dorsal aspect of the

Fig. 42-10 • Intraoperative photograph of an osteochondral fragment (arrow) of the proximal dorsomedial aspect of the proximal phalanx. MtIII, Third metatarsal bone.

MtIII, but they are not avulsion fractures. Proliferative changes often develop. Treatment is by surgical removal, but prognosis is guarded in racehorses.

A rare finding in the MTP joint is a loose fragment located in the distal aspect of the plantar pouch. In some horses, small defects in the dorsal aspect of the sagittal ridge of the MtIII can be seen radiologically. A small fragment may have detached and migrated to the plantar pouch. Large, loose fragments may exist for some time in the plantar pouch without causing lameness.

Fractures of the Proximal Phalanx

One of the most common major fractures in the MTP joint is midsagittal fracture of the proximal phalanx or other fractures with a midsagittal component. These fractures occur most often in racehorses but also occur in other sports horses. In racehorses, midsagittal fractures of the proximal phalanx occur in STBs equally in hindlimbs and forelimbs, but in TBs, forelimb fractures are most common. These fractures are discussed in Chapters 35 and 36. Horses with moderately comminuted fractures of the proximal phalanx, in which an intact fragment of bone (strut) spans the distance between the proximal and distal articular surfaces of the proximal phalanx, can be managed successfully and salvaged for breeding purposes using open reduction and internal fixation. Those with massive comminution without an intact strut can be salvaged, but use of transfixation pin casting or external skeletal fixation to maintain axial alignment is necessary. In a study of 64 horses with comminuted fractures of the proximal phalanx, 26 fractures involved the hindlimbs, and overall, 33 of 36 (92%) horses with moderately comminuted fractures managed by open reduction and internal fixation were considered to have successful outcomes (salvaged for breeding, pasture soundness, or light riding).³⁸ Twelve of 26 horses (46%) with severely comminuted fractures managed with external skeletal fixation or transfixation pin casting survived, but management was complicated and hospitalization was prolonged.³⁸

Dorsal Frontal Fractures of the Proximal Phalanx

Dorsal frontal fractures of the proximal phalanx occur much more commonly in the hindlimbs than in the forelimbs, and large osteochondral fragments in the forelimb may cause similar clinical signs. Size and depth of fracture appear different between forelimbs and hindlimbs; in the forelimbs, when dorsal frontal fracture occurs it is usually a long fracture beginning deep within the articular surface and extending distally, well into the diaphysis of the proximal phalanx, as compared with the typical fracture in the hindlimbs, which is 7 to 10 mm deep (from dorsal to plantar) and approximately 20 mm in length. They occur in both TB and STB racehorses. Dorsal frontal fractures may be more common in the right hindlimb. Although these fractures are reported to be more common in TBs,³⁹ in my experience the fracture is near equally as common in STBs and can be unilateral or bilateral. If a dorsal frontal fracture of the proximal phalanx is diagnosed scintigraphically, contralateral IRU of the dorsal proximal aspect of the proximal phalanx is commonly seen (Figure 42-11). IRU associated with a dorsal frontal fracture of the proximal phalanx must be differentiated from a midsagittal fracture. Midsagittal fractures are single-event injuries, but a dorsal frontal

Fig. 42-11 • A, Delayed (bone) phase lateral and plantar scintigraphic images of a metatarsophalangeal (MTP) joint of a 3-year-old Thoroughbred filly showing focal, intense increased radiopharmaceutical uptake (IRU) associated with the proximal dorsal aspect of the proximal phalanx (arrow) in the left hindlimb (LH). Mild-moderate IRU is seen in the right hindlimb, associated with early maladaptive or nonadaptive bone remodeling of the distal plantarolateral aspect of the third metatarsal bone. **B**, Flexed latero-medial digital radiographic image of the LH MTP joint showing the typical configuration of a nondisplaced dorsal frontal fracture of the proximal phalanx (arrows). Because the fracture is nondisplaced and there are no interposed fragments in the fracture line, this horse can be managed conservatively with an excellent prognosis.

fracture of the proximal phalanx may be caused by stress-related bone injury, because gradations of IRU are seen in the proximal phalanx and concomitant contralateral IRU occurs. Although bilateral fracture or evidence of stress-related bone injury can be seen bilaterally simultaneously, horses may develop contralateral fracture the next year. TB racehorses appear to be able to tolerate pain associated with dorsal frontal fractures better than STB racehorses; I have seen many that have raced with this fracture. There may be chronic proliferative changes and a displaced fracture in a TB horse that raced within the prior 10 days. Displaced fractures do not occur in STBs, and lameness may be noticed earlier than in the TB racehorse. Pacers are most likely to have an obvious fracture, whereas fractures in trotters may be scintigraphically active with only subtle radiological changes.

A dorsal frontal fracture of the proximal phalanx usually results in intermittent, severe lameness, but bilateral fractures may cause poor performance without causing obvious signs of lameness. Effusion is present but may be only mild unless fractures are displaced. The response to lower limb flexion is positive. Intraarticular or low plantar analgesia abolishes lameness in horses with complete or displaced fractures, but the low plantar technique should be used in those with stress-related bone injury or incomplete fractures. Radiographs reveal a single fracture line

that is best recognized in LM or flexed LM images. Fractures are usually on the dorsolateral aspect of the proximal phalanx, and if seen in oblique radiographic images, are best seen in the DM-PILO image, a position to keep in mind if surgical repair is contemplated. Fractures begin at the articular surface and course in a dorsodistal direction (see [Figure 42-11](#)). In TBs with displaced fractures an osteochondral fragment often is interposed between the main fracture fragment and the parent bone.

If fractures are nondisplaced, conservative management provides a good-to-excellent prognosis in both TBs and STBs. Horses are given 4 weeks of stall rest, followed by 4 weeks of stall rest with handwalking, then 4 to 8 weeks of turnout in a small paddock. Two treatment options are available for horses with displaced fractures. In those with large fragments and interposed osteochondral fragments, arthroscopic surgery is recommended to remove small osteochondral fragments and to repair the dorsal frontal fracture using one or two 3.5-mm screws. If the fracture cannot be reduced or is broken or small, the fragment should be removed. Prognosis is good to excellent for future racing, but horses may drop in class, particularly those with compensatory or numerous lameness problems. Long dorsal frontal fractures, such as those that occur in the forelimbs, cause acute, severe lameness and should be repaired (see Chapter 36).

Fractures of the Proximal Sesamoid Bones

Overall, fractures of the PSBs appear to be near equally distributed between the metacarpophalangeal and MTP joints, but distribution depends on fracture configuration. In STB racehorses, distribution of all PSB fractures likely favors the hindlimbs. In a study of TB racehorses less than 2 years old, 92% of apical fractures of the PSBs occurred in the hindlimbs, and overall 84% of horses raced after arthroscopic surgical removal of the fracture fragments, a prognosis similar to racing performance of maternal siblings.⁴⁰ In another study, in TB racehorses that were 2-year-olds or older, 64% of apical fractures of the PSBs occurred in the hindlimbs, and prognosis for racing after arthroscopic removal of hindlimb fractures was 83%.⁴¹ In both studies, prognosis for racing was better when fractures occurred in a hindlimb than in a forelimb.^{40,41} Apical fractures of the PSBs are more common in the hindlimb of STBs and most often involve the lateral PSB. Fractures of the abaxial aspect of the PSBs, sometimes including an apical component, occur most commonly in the medial PSB in the forelimb. Midbody and basilar fractures of the PSBs appear to be more common in the forelimbs. Fractures of the PSBs can be traumatic or pathological. Young racehorses develop acute lameness and fracture without preexisting disease of the PSB or SL. However, the PSB undergoes extensive remodeling similar to the MtIII, and it is possible, perhaps even likely, that these fractures represent a form of stress-related bone injury. In older racehorses and in some nonracehorse sports horses, preexisting radiolucent and proliferative sesamoiditis and suspensory branch desmitis are present, and fractures of the PSB appear to develop as a pathological, secondary, end-stage injury. In some nonracehorse sports horses, fracture occurs as a single event without preexisting injury. Prognosis depends on the size of the fracture fragment and the degree of suspensory desmitis. In STB racehorses, prognosis is better in pacers than

in trotters, and prognosis is poor in horses developing fractures early in training before racing begins (see Chapter 36). The prognosis is good in nonracehorse sports horses without preexisting injury. Arthroscopic surgical removal of apical, abaxial, and small basilar fracture fragments and repair of large basilar and midbody fractures are recommended (see Chapter 36).

Fractures of the Distal Aspect of the Third Metatarsal Bone

Condylar fractures of the distal aspect of the MtIII occur less frequently than those of the McIII (see Chapter 36). In a study of 135 horses with condylar fractures, 81% and 85% involved the forelimbs and lateral condyles, respectively.⁴² Lateral and medial condylar fractures of the MtIII occur, but lateral fractures are most common. Lateral condylar fractures can be short and incomplete, long and incomplete, or long and complete. Bilateral fractures occasionally occur simultaneously. Condylar fractures are primarily racing injuries. In a study of TB, STB, and Arabian racehorses, TBs were overrepresented and STBs underrepresented; TBs had significantly more lateral and forelimb fractures than STBs.⁴³ Clinical signs are commensurate with the length and degree of displacement. Medial condylar fractures can be short, incomplete, and difficult to diagnose. However, most commonly lameness is severe and radiographs reveal that the fracture is long and incomplete but goes straight proximally to end abruptly in the diaphysis, forms a Y-shaped pattern ([Figure 42-12](#)), or spirals proximally to end near or at the tarsometatarsal joint ([Figure 42-13](#)). Occult fissure lines and spiraling should always be suspected, and it is critical to know the location of the fracture before horses are transported and prognosis is discussed. Horses with medial condylar fractures are at extreme risk for fracture propagation or comminution. Even after surgical repair, horses are at risk during recovery from general anesthesia and early in the postoperative period. In 15 horses with medial condylar fractures of the MtIII, the fractures of 12 horses were repaired, two horses suffered catastrophic fracture during recovery from general anesthesia, and three horses developed complete fracture within 4 days after surgery.⁴⁴ Recovery from general anesthesia should be assisted and may best be performed using a pool recovery system, if available.

Horses with short, incomplete lateral and medial condylar fractures can be managed conservatively or can undergo surgical repair. Those with longer spiral or medial condylar fractures with a Y shape should undergo surgical repair. This repair can be accomplished by use of a combination of open observation of the fracture line and either screw fixation (see [Figure 42-13](#)) or a combination of screws and a dynamic compression plate or locking compression plate (see [Figure 42-12](#)). Prognosis depends on whether fractures are medial or lateral, whether they are displaced or nondisplaced, and whether a plate or numerous screws are used for repair. If fractures heal and plates (if used) are removed, prognosis for racing is favorable, but horses will often drop in race class or fail to reach full potential.

Sesamoiditis

In the STB, hindlimb sesamoiditis is most common in the lateral PSB but can occur medially and be a source of occult

Fig. 42-12 • Digital radiographic images before and after surgery of a 2-year-old Thoroughbred filly with a nondisplaced, spiral fracture of the third metatarsal bone (MtIII) beginning at the medial condyle. **A**, Dorsoplantar radiographic image (lateral is to the right) showing the fracture line (*arrow*) beginning from the medial condyle and propagating proximally in a slight spiral fashion. Both dorsal and plantar cortical lines can be seen. **B**, Dorsal 45° medial-plantarolateral radiographic image showing that the fracture line abruptly becomes oblique (*arrows*) and stops in the middiaphyseal region. This horse would be at risk for catastrophic injury without repair, and during or immediately after surgery if repair were performed with bone screws alone. **C**, Postoperative dorsoplantar radiographic image showing repair of the fracture using screws placed in lag fashion and a 12-hole limited-contact dynamic compression plate applied to the lateral aspect of the MtIII, using a dorsal, transtendinous approach. The distal two screws and the first four distal screws in the plate have been placed in lag fashion. The plate was later removed at 3 months after surgery, and the filly raced successfully as a 3-year-old.

MTP joint lameness. In TBs sesamoiditis is most commonly observed in the forelimb. TBs can have obvious radiolucent lines in the PSBs in hindlimbs that are often asymptomatic. Disparity between limbs, rather than size or number of radiolucent lines, was found in a study to be most important in determining clinical significance in TBs; horses with three or more channels were less likely to race as 2-year-olds and had decreased earnings per start.⁴⁵ In another study, in the STB racehorse the presence of one to three or more radiolucent defects less than or equal to 1 mm in width was not associated with lameness referable to the PSBs, but horses with wide, abnormally shaped defects developed lameness from sesamoiditis.⁴⁶ Conversely, Grøndahl and colleagues reported that of 753 young STBs that underwent radiographic examination before training, 21 horses had severe sesamoiditis, fractures, or enlarged PSBs, but a correlation between sesamoid pathology and lameness or decreased racing performance and earnings could not be made. In that study hindlimb PSBs were affected in only six horses, and lameness developed in 14 horses.⁴⁷ Although lameness could not be directly attributed to

changes in the PSBs, in some horses MTP joint lameness was diagnosed, and perhaps compensatory lameness developed as a result of chronic, low-grade or high-speed lameness in these trotters. Seven of 21 horses had concomitant osteochondral fragments of the plantar/palmar process of the proximal phalanx, although a clear relationship could not be established.⁴⁷

Radiolucent Defects of the Axial Border of the Proximal Sesamoid Bones

See Chapters 72 and 74 for a discussion of radiolucent defects of the axial border of the PSBs.

Flexural Deformity of the Metatarsophalangeal Joint

Dorsal subluxation of the MTP joint (buckle or knuckle forward) occurs in horses with flexural deformity. Intermittent subluxation occurs in those with mild deformity, but some horses with more severe deformity maintain the MTP joint in partial flexion. Horses with chronic, severe tenosynovitis of the DFTS with extensive adhesions may

Fig. 42-13 • Dorsoplantar radiographic images of the metatarsophalangeal (MTP) joint and the entire metatarsal region. There is a spiral fracture of the third metatarsal bone (*arrows*) beginning at the medial condyle of the third metatarsal bone (medial is the left) in the MTP joint and extending to near the tarsometatarsal joint (confirmed at surgery after subperiosteal dissection) before (**A**) and after (**B**) surgery.

develop progressive, severe flexural deformity. Desmopathies of the accessory ligament of the DDFT may cause flexural deformity (see Chapter 71). In some horses, application of an extremely elevated heel shoe (e.g., 5 to 8 cm) may help alleviate pain (see Chapter 59).

Dropped fetlock or plantar subluxation (hyperextension) occurs in horses with severe chronic suspensory desmitis or those with severe, acute tearing of the superficial digital flexor tendon (SDFT), the DDFT, or both the SDFT and DDFT.

Soft Tissue Injuries of the Metatarsophalangeal Joint and Fetlock Region

Proliferative Synovitis

Proliferative synovitis (i.e., enlarged synovial pad or villonodular synovitis) occurs in the dorsal aspect of the MTP joint in horses with chronic OA. However, it is much less

common than in the metacarpophalangeal joint and is a rare primary cause of pain (see Chapter 36).

Luxation and Subluxation: Tearing of a Collateral Ligament

Complete disruption of a collateral ligament causes luxation and results in severe, non-weight-bearing lameness and usually obvious valgus or varus deformity. This injury is more common in adult horses, because physeal fractures of the distal aspect of the MtIII and proximal phalanx are more likely in foals. Initially little swelling occurs, but within a few hours soft tissue swelling can be prominent and manipulation of the joint reveals instability. Diagnosis is confirmed radiologically using DPI and stressed DPI images. Radiographs should be examined carefully for the presence of concurrent fractures on the contralateral or plantar aspects of the joint. Ultrasonography is used to identify the injured portion of the collateral ligament and extent of injury. After manual reduction with the horse under general anesthesia, a fiberglass cast should be applied. The cast should be changed within 7 to 10 days, because swelling resolves and the cast loosens. Cast coaptation should be maintained for 8 to 10 weeks, and then a heavy bandage should be applied. If crushing of the opposite side or plantar aspect of the joint did not occur, prognosis for soundness is guarded to fair. OA and chronic desmitis of the collateral ligament are possible. In a study, eight of 17 horses with rupture of the collateral ligaments of the metacarpophalangeal or MTP joints had hindlimb injury, and the lateral collateral ligament was more commonly affected. The presence of avulsion fracture fragments did not negatively affect prognosis. Ultrasonographic examination was useful in characterizing injury. Eight of 16 horses managed with external coaptation returned to some form of rider exercise.⁴⁸

Collateral Desmitis

Primary injury of the collateral ligament without luxation is rare in my experience. Clinical signs include firm soft tissue swelling and ultrasonographic evidence of desmitis in horses with lameness that is abolished by low plantar analgesia. Avulsion fractures may occur as a result of trauma.

Suspensory Desmitis

See Chapter 72 for a discussion of suspensory desmitis.

Distal Sesamoidean Ligament Injury

See Chapter 72 for a discussion of injury of the distal sesamoidean ligaments.

Tenosynovitis of the Digital Flexor Tendon Sheath

See Chapter 74 for a discussion of tenosynovitis of the DFTS.

Deep Digital Flexor Tendonitis

See Chapters 70 and 74 for a discussion of deep digital flexor tendonitis.

Chapter 43

The Metatarsal Region

Mike W. Ross

The metatarsal region, like most of the distal hindlimb, has received little attention in previous lameness textbooks. However, it is a common source of lameness problems and should not be overlooked, especially in view of the high incidence of suspensory desmitis in sports horses.

ANATOMY

The metatarsal region is bordered by the tarsometatarsal joint proximally and the metatarsophalangeal joint distally. The large third metatarsal bone (MtIII) provides all structural support and weight bearing and articulates predominantly with the third tarsal bone proximally and the proximal phalanx and proximal sesamoid bones (PSBs) distally. A prominent nutrient foramen in the MtIII should not be mistaken for a fracture and is usually located slightly higher than that of the third metacarpal bone (McIII).¹

The second metatarsal bone (MtII) and fourth metatarsal bone (MtIV) are commonly referred to as the *medial* and *lateral splint bones*, respectively. The MtII articulates with the combined first and second tarsal bones proximally and ends distally with an enlarged “bell.” The MtIV articulates with the fourth tarsal bone proximally but transmits less load than the MtII. The dorsal metatarsal artery runs obliquely, in a distoplantar direction, in the proximal lateral aspect of the metatarsal region and then parallel and close to the dorsal aspect of the MtIV as it courses distally in the midmetatarsal region. The dorsal metatarsal artery then courses deep to the MtIV and must be avoided during distal splint osteotomy. I examined one horse in which the dorsal metatarsal artery coursed through a bony and fibrous ring-like foramen in the distal aspect of the MtIV and was inadvertently severed during osteotomy of the MtIV. Because the dorsal metatarsal artery is superficial, it can be lacerated from wounds in the lateral metatarsal region. Bleeding can be profound, and the ends of a lacerated dorsal metatarsal artery should be ligated unless anastomosis is performed with the horse under general anesthesia. Collateral circulation develops if ligation is necessary. The long plantar ligament attaches to the proximal aspect of the MtIV.

The orientation of the metatarsal bones is clinically important. The proximal aspect of the MtIV is large and is located in a more plantar location than its counterpart, the fourth metacarpal bone (McIV). This orientation makes it impossible to palpate the normal proximal and midbody portions of the suspensory ligament (SL). Therefore unless it is grossly enlarged, the SL cannot be palpated, and conditions such as mild-to-moderate suspensory desmitis can easily be missed, particularly if lameness is chronic and signs of acute inflammation are not present.

Dense metatarsal fascia attaches to the abaxial margins of the MtII and the MtIV and encircles the SL, deep digital

flexor tendon (DDFT), and superficial digital flexor tendon (SDFT). A thinner fascia, the suspensory laminar fascia, lies superficial to the SL, deep to the DDFT. The metatarsal and laminar fascial layers appear confluent at the attachment on the MtII. Swelling of the SL within these fascial compartments can cause pain by compression of the adjacent metatarsal nerves.² The SL has a broad origin on the proximal, plantar surface of the MtIII and a small attachment to the distal tarsal bones. The hind SL is slightly longer and thinner than the front SL, and muscle content may be higher in hindlimbs compared with forelimbs, which can complicate ultrasonographic examination.³ It has been suggested that the higher incidence of suspensory desmitis in Standardbreds (STBs) than in Thoroughbreds (TBs) is related to higher muscle content, but this is unproven.³

The plantar surface of the MtIII and the origin of the SL are oblique and not parallel to the dorsal surface of MtIII. During ultrasonographic examination, care should be taken to account for obliquity and to position the transducer perpendicular to SL fibers (see Chapter 72). The SL is bordered by the MtII and the MtIV and is thus trapped within a bony and dense soft tissue encasement. In the midmetatarsal region the body of the SL can be palpated as it emerges from this bony encasement and courses distally to divide into the medial and lateral branches that attach to the abaxial border of each PSB. The accessory ligament of the DDFT (ALDDFT) is usually present and is a variably sized structure ranging from thin to thick and occasionally has two or three parts; in a small proportion of horses (10 of 165, or 6.1%) there was no identifiable ALDDFT.⁴ Although the ALDDFT is anatomically present in most horses, injury is rare (see Chapter 71). Desmotomy to manage flexural deformity is rarely performed and generally would be ineffective because of the small size of the ALDDFT. I examined an aged Quarter Horse gelding with enlarged ALDDFTs with unusual flexural deformity characterized by intermittent, dynamic heel elevation; during walking the heels would land flat, but during standing the heels elevated bilaterally (see Chapter 71). I severed the ALDDFT in each hindlimb, and although improvement was seen temporarily, flexural deformity recurred. The DDFT is located plantar to the SL for most of the metatarsal region, but in the proximal metatarsal region it is positioned plantaromedially. The SDFT is located plantar to both the SL and DDFT. Because the tarsal sheath ends in the proximal metatarsal region, distention can sometimes be palpated (see Chapter 76). The digital flexor tendon sheath (DFTS) begins in the plantar, distal third of the metatarsal region and encompasses the DDFT and SDFT (see Chapter 74).

In the proximal third of the metatarsal region the lateral digital extensor tendon joins with the long digital extensor tendon, and the combined tendons course distally. The fibularis tertius and cranialis tibialis attach to the proximal, dorsal, and medial aspects of the MtIII. Osseous proliferation and fracture can occur at these locations.

Distal continuation of the superficial fibular and saphenous nerves provides dorsal skin sensation. The tibial nerve divides to form the medial and lateral plantar nerves in the plantar tarsal region. The lateral plantar nerve, which courses plantar to the origin of the SL, gives off a deep

Fig. 43-1 • Intraoperative photograph of a Warmblood gelding with chronic, recurrent proximal suspensory desmitis of the left hindlimb after a surgical approach to sever the deep branch of the lateral plantar nerve (LPI n). The horse is in right lateral recumbency (proximal is to the right and dorsal is uppermost), the Kelly forceps is positioned at the level of the tarsometatarsal joint (Tmt Jt), and the Senn retractors are positioned deep to the metatarsal fascia and superficial digital flexor tendon, both of which are retracted in a plantar direction. The parent lateral plantar nerve (LPI n) coursing distally originates from the tibial nerve proximal to the tarsus and divides into a deep branch, a segment of which is removed during neurectomy, and then continues distally as the lateral plantar nerve. The deep branch further divides within the suspensory ligament and proximal metatarsal region to innervate the proximal aspect of the suspensory ligament and the plantar cortex of the third metatarsal bone; it then divides into lateral and medial plantar metatarsal nerves, which continue distally to innervate the fetlock joint (not shown, deep to the suspensory ligament).

branch that innervates the proximal aspect of the SL and gives off branches, which continue distally as the lateral and medial plantar metatarsal nerves that course on the axial aspects of each respective splint bone (see Figure 10-22; Figure 43-1). Neurectomy of the deep branch of the lateral plantar nerve provides analgesia of the origin of the SL and the plantar cortex of the MtIII and partial analgesia of sites more distal to the level of and including the metatarsophalangeal joint. Accurate interpretation of diagnostic analgesia is critical when planning this surgical procedure. Neurectomy has received considerable attention recently as a surgical approach for management of proximal suspensory desmitis (PSD; see later).^{5,6} Histological changes consistent with nerve compression have been identified in horses undergoing neurectomy of the deep branch of the lateral plantar nerve, and nerve compression was proposed as a possible cause of residual pain in horses even after desmitis resolved.⁶ In that study, 62% of horses returned to soundness after neurectomy,⁶ whereas in a different study 19 of 20 horses treated by neurectomy and laminar fasciotomy returned to the previous level of performance.⁵ The deep branch of the lateral plantar nerve that was examined histologically⁶ lies within the dense metatarsal but outside the laminar fascial planes. Recognition of neuritis in this segment indicates that compression of the deep branch may be occurring within this fascial compartment. The lateral plantar nerve and its counterpart, the medial plantar nerve, continue distally between the SL and DDFT.

Conformation

Sickle-hock and more important straight hindlimb conformation predispose to metatarsal region lameness (see Chapter 4).

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF LAMENESS IN THE METATARSAL REGION

There are no pathognomonic historical findings related to metatarsal region pain causing lameness. Palpation of the metatarsal region should be done with the horse in standing and non-weight-bearing positions. The metatarsal region cannot be adequately palpated when the horse is standing, because soft tissue structures in the proximal metatarsal region are not readily palpable in this position. Careful palpation for signs of inflammation and bony swelling should be performed with the limb in both positions. Even when the limb is flexed, it is still difficult to define the SL and DDFT proximally. However, it is possible to apply pressure over the proximal aspect of the SL to check for a painful response. In some horses with PSD, edema may be present or the area may feel full or slightly thickened, but dense fascia covering the SL and DDFT prevents expansion, and swelling may go undetected. A painful response to deep palpation over the proximal aspect of the medial splint bone and distal aspect of the tarsus, referred to as the *Churchill test*, may indicate the presence of referred pain and primary distal hock joint lameness, but in my experience this is a nonspecific test. Many horses with hindlimb lameness originating from sites other than the distal hock joints manifest a positive response to compression of both the medial and lateral splint bones and distal, medial aspect of the tarsus. Palpation of the dorsal cortex of the MtIII may reveal pain in trotters or other horses that interfere and may be an important finding, but palpation may not necessarily localize the primary source of pain that is causing lameness. Careful palpation of the abaxial and axial aspects of both splint bones is necessary to uncover hidden splint exostoses. Even subtle enlargement of the SL body, as it emerges from the bony encasement of the splint bones, that is accompanied by a painful response can indicate early suspensory desmitis. Both branches of the SL and attachments to the PSBs should be carefully palpated. Horses with a history of curb may develop progressive SDF tendonitis in the proximal metatarsal region, but this can easily be overlooked unless the area is carefully palpated (see Chapters 6, 69, and 78).

Diagnostic Analgesia

The high plantar perineural block (see Chapter 10) should be used to localize pain to the metatarsal region. Medial and lateral plantar nerves and medial and lateral plantar metatarsal nerves are blocked just distal (approximately 1.5 cm) to the tarsometatarsal joint (see Chapter 10). Variations of this block are often used, but it is important to recognize that subtarsal analgesic techniques targeting the lateral plantar nerve, or its deep branch, will not block the medial plantar nerve, and false-negative results could be obtained. More important, false-positive results incriminating the proximal aspect of the SL as a source of pain can occur. Subtarsal analgesia should be performed only

after results of low plantar analgesia are observed, because most injection techniques in the subtarsal region are likely to desensitize the plantar metatarsal nerves, important contributors to innervation of the metatarsophalangeal joint. An injection technique was recently described for the diagnosis of PSD; the lateral plantar nerve is blocked approximately 15 mm distal to the head of the MtIV, just axial to the MtIV, at a depth of 25 mm.⁷ Although in theory this block is done in close proximity to the deep branch of the lateral plantar nerve, it is within the same fascial compartment as the parent branch, leading to the possibility of blocking this important contributor to distal limb innervation. If completed as a stand-alone technique without first performing low plantar analgesia, subtarsal analgesia may lead the clinician to the erroneous impression that pain is emanating from the proximal aspect of the SL. Management of horses with PSD by desmoplasty and fasciotomy was recently described, but criteria for inclusion of cases suggested that pain was localized to the proximal metacarpal or metatarsal region by use of only subcarpal or subtarsal analgesia without first blocking the distal aspect of the limb.⁸

In the forelimb, distal palmar outpouchings of the carpometacarpal joint complicate interpretation of diagnostic analgesic techniques. In the hindlimb, distal plantar outpouchings of the tarsometatarsal joint can potentially be penetrated when high plantar analgesic techniques are performed, but outpouchings of the joint were not seen in magnetic resonance images of cadaver specimens in a study comparing imaging modalities in the plantar metatarsal region.⁹ In an *in vivo* radiographic contrast study in only 5% of limbs was the tarsometatarsal joint inadvertently penetrated when injection mimicking high plantar analgesia was performed at a level of 1.5 cm distal to the tarsometatarsal joint, although in the same study inadvertent penetration of the tarsal sheath occurred in 40% of limbs.¹⁰ Care must be taken when interpreting diagnostic analgesia.

Imaging Considerations

Routine radiographic examination includes the dorso-plantar (DPI), lateromedial (LM), dorsolateral-plantaromedial oblique (DL-PIMO), and dorsomedial-plantarolateral oblique (DM-PILO) images. In a DPI image of the proximal aspect of the MtIII, there is a normal area of mild increased radiopacity that should not be interpreted as modeling that is associated with stress reaction of the origin of the SL (Figure 43-2). Accurate assessment of the proximal aspect of the MtIII for the presence of increased radiopacity or avulsion fracture requires that radiographic views be centered at this level.

Pool and delayed (bone) phase scintigraphic examination is quite useful to differentiate bone from soft tissue injury in horses with proximal plantar metatarsal pain and osteoarthritis. It is also useful to differentiate other conditions of the tarsometatarsal joint from those involving the proximal aspect of the MtIII. Focal increased radiopharmaceutical uptake (IRU) seen in delayed (bone) phase images involving the proximal plantar aspect of the MtIII is the most important scintigraphic finding in the metatarsal region. In TB and STB racehorses there is normally mild to mild-moderate IRU of the dorsal cortex of the MtIII, from the most proximal aspect to the mid-to-distal diaphysis. This finding was originally proposed to be age dependent

Fig. 43-2 • Dorsoplantar radiographic image showing the normal coarse trabecular pattern (arrows) seen in the proximal aspect of the third metatarsal bone, which can be mistaken for increased radiopacity associated with the suspensory attachment. This Standardbred racehorse had a sagittal fracture of the talus. Note the radiolucency of the talus (open arrow).

because the dorsal cortex of the McIII could be “seen” scintigraphically as a normal finding in young but not older TB racehorses.¹¹ In a population of predominantly sports horses and few racehorses the dorsal cortex was evident visually and with use of profile analysis in all horses regardless of age.¹² When normal plantar scintigraphic images of the proximal metatarsal region are evaluated, there is usually asymmetrical radiopharmaceutical uptake (RU), with greater RU of the lateral aspect involving the lateral aspect of the MtIII and the MtIV. A central area of increased radiopacity seen radiologically (see Figure 43-2) does not appear to be active scintigraphically in normal horses. Asymmetrical RU was confirmed in a recent scintigraphic study of the proximal metacarpal and metatarsal regions in normal horses.¹³ Using region of interest analysis there was significantly higher RU in the lateral aspect of the metatarsal region compared with the medial aspect in plantar images, and significantly higher RU in the right proximal metatarsal region compared with the left. In lateral images there was maximum RU in the central and plantar aspect of the proximal metatarsal region. There was no effect of age on RU.¹³ In horses with PSD, visual appraisal and profile analysis of scintigraphic images failed to reveal abnormalities in most of 126 horses with forelimb or hindlimb lameness, but quantitative analysis using region of interest analysis revealed greater RU ratios in plantar images of lame limbs compared with nonlame limbs.¹⁴ Given that PSD is

primarily a soft tissue injury, the lack of scintigraphic findings is easily understood; that many horses have chronic or recurrent hindlimb PSD could explain mild scintigraphic abnormalities found in plantar metatarsal images.

Ultrasonographic evaluation should be performed to evaluate the plantar soft tissue structures, the most important of which is the SL (see Chapters 16, 72, and 78). Computed tomography (CT) can be useful to evaluate complex fractures in the metatarsal region, the plantar cortex of the MtIII, and bony exostoses of the metatarsal bones (see Chapter 20). CT was useful in imaging new bone formation on the proximal plantar aspect of the MtIII in three horses with PSD that were successfully treated by ostectomy and osteostixis of the MtIII.¹⁵ Magnetic resonance imaging (MRI) is quite valuable in the diagnosis of PSD and for identifying adhesions between the MtII or the MtIV and the SL (see Chapters 21 and 37). In a study comparing the results of ultrasonography, MRI, and histology of the SL in the forelimb and hindlimb, the heterogeneity of the SL including the presence of muscular and adipose tissue, artifacts, and variable size were thought to be limitations of ultrasonographic examination.⁹ In the hindlimb the SL had a single large area of origin on the MtIII with a few fibers originating from the distal row of tarsal bones, was mildly bilobed in appearance, and was located slightly more laterally on the MtIII than at the corresponding position in the forelimb; significantly more muscular tissue was found laterally and similar sizes of the lateral and medial lobes were found.⁸ There was good correlation in morphology between MRI and histology, but cross-sectional area measurements were significantly higher with MRI than with either ultrasonography or histology, and histological cross-sectional area measurements were significantly higher than those obtained with ultrasonography.⁹ At the origin of the SL in the hindlimb, ultrasonographically determined cross-sectional area measurements were less than half of those determined using histology and MRI. Although relative measurements between limbs obtained using ultrasonography may be comparable, measurements between horses must be interpreted with caution.⁹ Measurement of plantar-to-dorsal thickness, however, was similar using all three modalities and may be the most useful measurement with which to compare sizes within and between horses.⁹ Ultrasonographic examination of the proximal aspect of the SL will likely underestimate cross-sectional area, and heterogeneity must be interpreted carefully. MRI was useful in characterizing injury and formulating management options in the proximal metacarpal and metatarsal regions of 45 horses, of which 13 horses had hindlimb PSD.¹⁶

SPECIFIC CONDITIONS OF THE METATARSAL REGION

Bucked and Sore Shins: Dorsal Cortical Fractures of the Third Metatarsal Bone

Modeling and remodeling of the dorsal cortex of the MtIII occur similarly to that of the McIII, but differences in load distribution between forelimbs and hindlimbs account for the relative lack of clinical signs associated with this process in the hindlimbs. Scintigraphic examination often reveals mild, diffuse IRU in the dorsal cortex of the MtIII in TB

racehorses (see earlier discussion), but clinical signs of bucked shins are rare. In trotters common findings are pain on palpation, wounds and abrasions, and in some horses bony swelling that is associated with interference injury in the dorsal or dorsal medial metatarsal region. Although these areas are painful to palpation, most sites are a sign rather than the cause of a high-speed gait deficit. Finding evidence of interference injury, however, is quite important, because interference is often a sign of ipsilateral forelimb lameness and can be a cause of horses making breaks (going off stride). Dorsal cortical fractures are rare but can occur in TB and STB racehorses.

Medial and Lateral Condylar and Spiral Fractures of the Third Metatarsal Bone

Medial and lateral condylar and spiral fractures of the MtIII are discussed in Chapter 42.

Midshaft, Simple, or Comminuted Fractures of the Third Metatarsal Bone

Diaphyseal fractures of the MtIII can result from propagation and displacement of medial condylar fractures. Direct trauma is the most common cause, often from kicks by other horses. Complete fracture of the MtIII occurs in foals and adult horses. Critical prognostic factors are degree of comminution; proximity of the fracture to the metatarsophalangeal joint and tarsometatarsal joints; integrity of the vascular supply; whether the fracture is open or closed; degree of contamination if open; and the horse's age, value, performance level, and intended use. Prognosis for adult horses with open, comminuted fractures of the MtIII is poor, but in those with closed, mildly comminuted or oblique fractures, repair is possible and prognosis is guarded to fair. Often, financial considerations are paramount in determining success with fractures of the metatarsal region in adult horses, because even if fractures are open and comminuted, advanced methods of repair and use of techniques such as intravenous regional limb perfusion may improve prognosis. The locking compression plate, designed with locking screws to provide a fixed-angle construct not dependent on the plate-bone interface being in compression, is ideal to use in horses with comminuted fractures and can be thought of as an internal-external fixator. This advanced system was successfully used in two horses recently and would be my choice if internal fixation was to be used in repair of a MtIII fracture.¹⁷ Horses with open fractures with gross contamination have a grave prognosis, regardless of age and degree of comminution, but those with small areas of skin loss and minor contamination can be successfully managed. Repair in horses with comminuted fractures involving the tarsometatarsal joint is difficult, but transfixation pin casts using the distal tibia and distal aspect of the MtIII could be considered. In foals, vascular supply of the limb distal to a fracture is a concern and should be assessed clinically or by using angiography or Doppler ultrasonography. Prognosis in foals with simple or mildly comminuted midshaft MtIII fractures repaired using one or two dynamic compression plates is fair to good (Figure 43-3). In foals, external coaptation often causes profound flexor tendon laxity and should be avoided. External skeletal fixation by using pins and

Fig. 43-3 • This open (mildly contaminated) midshaft fracture of the third metatarsal bone in a 4-month-old Thoroughbred colt was successfully managed using two dynamic compression plates and a half-limb bandage. **A**, The preoperative and **B**, postoperative appearance of the third metatarsal bone are shown. The plates were removed 4 months later.

sidebars of casting material or acrylic is possible in a foal. In adult horses, methods of stabilization and repair include internal fixation using two bone plates, locking compression plates or a combination of limited-contact dynamic and locking compression plates, transfixation pin casts in combination with internal fixation, and casts alone.

Of 25 horses with MtIII or McIII fractures that were managed with internal fixation, external coaptation, or both, age, sex, weight, and the limb affected were not related to outcome, but affected horses were younger than the general hospital population. Seventeen horses had open fractures, and infection was the most common complication after surgery.¹⁷ Nonunion in an infected fracture was the most common reason for failure (seven horses). Of 24 horses in which outcome was determined, 16 (67%) had healed fractures and 12 (50%) horses were sound for the intended use.¹⁷ Intended use was not defined; therefore prognosis in foals for future racing could not be determined. Of 37 horses and foals undergoing transfixation pin casting for management of difficult fractures, 10 of 15 horses (67%) in which fractures involved the McIII or the MtIII survived, a prognosis level similar to that seen with internal fixation.^{18,19} Five of six horses, including both foals, managed with transfixation pin casting of the MtIII fractures survived.¹⁹ Transfixation pin casting is often chosen when fractures are difficult or open, when there is gross contamination, and when financial constraints pre-

clude use of expensive implants such as the locking compression plates and screws.

Physeal Fractures of the Distal Aspect of the Third Metatarsal Bone

The most common fracture of the distal MtIII physis is a Salter-Harris type II fracture, but various other fractures can occur. These fractures are usually quite stable, but perfect reduction is difficult to achieve. Fracture reduction and external coaptation are usually successful, but insertion of one or two 3.5- or 4.5-mm bone screws in the metaphyseal component may help stabilize the fracture and reduce the time necessary for external coaptation. Even short periods of cast immobilization in foals can cause rapid onset of flexor tendon laxity. Cast-bandage and bandage-splint combinations are preferred in young foals that are only several weeks old.

Incomplete Longitudinal Fractures of the Plantar Aspect of the Third Metatarsal Bone and Stress Reactions

Incomplete longitudinal fractures of the plantar cortex of the MtIII occur considerably less frequently than those of the McIII. Stress reactions of the MtIII, defined as focal areas of IRU without radiological confirmation of fracture, occur as part of a continuum of stress-related bone injury at the origin of the SL. Combined MtIII injury and PSD worsens prognosis, and it is important to establish whether injury involves bone, soft tissue, or both (see Chapters 37 and 72).

Transverse Stress Fractures of the Distal Aspect of the Third Metatarsal Bone

Transverse stress fractures of the distal aspect of the McIII are described in Chapter 37. I have not recognized this specific fracture type in the MtIII.

Avulsion Fractures of the Third Metatarsal Bone Associated with the Origin of the Suspensory Ligament

Avulsion fractures of the MtIII that are associated with the origin of the SL are frequently seen and can be solitary injuries or associated with PSD. Horses can have acute-onset or chronic mild-to-moderate hindlimb lameness, depending on size and duration of fracture. Fractures occur most commonly in dressage horses, jumpers, and STB racehorses. Local signs of swelling are usually absent, and diagnostic analgesia is essential for localization of pain. Focal areas of IRU are seen that are roughly triangular and involve the proximal plantar aspect of the MtIII (Figure 43-4). It is important to differentiate IRU from that seen in the tarso-metatarsal joint, but concomitant IRU in both areas is not unusual. A well-defined fracture is often not detectable radiologically, and usually only suspicious areas of radiolucency and increased radiopacity are seen. Bilateral avulsion fractures or stress reactions occur. Conservative management using a progressive increase in exercise without turnout is usually successful. Recurrence is common and most likely in horses that have associated PSD (see Chapter 72).

Fig. 43-4 • Delayed (bone) phase, lateral scintigraphic image showing focal, triangular increased radiopharmaceutical uptake typical of an avulsion fracture of the third metatarsal bone that is associated with the origin of the suspensory ligament.

Articular Fracture of the Dorsoproximolateral Aspect of the Third Metatarsal Bone

Articular fracture of the dorsoproximolateral aspect of the MtIII occurs primarily in STB and TB racehorses.^{20,21} Acute onset of lameness is common, but a history of either chronic, undiagnosed hindlimb lameness or lameness referable to the distal hock joints is usually uncovered. This fracture occurs most commonly in horses with sickle-hock conformation, a conformational abnormality that predisposes to dorsal and plantar tarsal and proximal metatarsal injury, and may worsen prognosis. This fracture occurs most frequently in horses in the later stages of training, but often before racing, a clinical characteristic that may worsen prognosis. Acute soft tissue swelling is rare. A small bony enlargement is often palpable but is easy to miss. Horses exhibit a positive response to upper limb flexion and to focal, deep pressure over the dorsolateral aspect of the MtIII. Lameness partially resolves after intraarticular analgesia of the tarsometatarsal joint or perineural analgesia of the fibular and tibial nerves. Initial radiological examination reveals the presence of bony proliferation, indicating that bone modeling preceded acute fracture (Figure 43-5). Incomplete fractures are most common, but complete and mildly displaced fractures also occur. Scintigraphic examination is useful in differentiating this fracture from other conditions involving the tarsometatarsal joint and those involving the proximal plantar aspect of the MtIII. Radiographs and scintigraphic images of the contralateral hindlimb often reveal similar but less pronounced changes.

Because proliferative changes precede fracture, it is presumed that the cause involves chronic fatigue and stress-related bone injury. Attachment of the tendons of the

Fig. 43-5 • Dorsomedial-plantarolateral xeroradiographic image of the hock and proximal metatarsal region of a Standardbred racehorse. There is an articular fracture of the dorsoproximolateral aspect of the third metatarsal bone (MtIII) (arrows). Note the bone modeling of the proximal aspects of the MtIII that preceded the fracture.

fibularis tertius and cranialis tibialis muscles likely contributes substantially to bone stress and may play a role. Concomitant radiological evidence of osteoarthritis involving the dorsal aspect of the tarsometatarsal and centrodistal joints and dorsoproximolateral fracture of the MtIII is common.

Conservative management is advised in horses with incomplete fractures, but in those with displaced fractures, internal fixation using one or two 3.5-mm bone screws placed in lag fashion is advised. If horses raced before fracture, the prognosis for future racing is good but only fair to guarded for returning to or sustaining racing in the same class. Horses that develop this fracture before actual racing begins have a poor prognosis. When horses return to training or racing, progressive osteoarthritis of the tarsometatarsal and centrodistal joints appears to be a limiting factor even when the fracture heals and proliferative changes on the MtIII smooth.

Exostoses of the Second, Third, and Fourth Metatarsal Bones

Exostoses of the metatarsal bones (splint exostoses, splints) occur considerably less commonly than those involving the metacarpal bones, but they can cause lameness, or in racehorses, high-speed soreness. However, it is common to find large exostoses involving the proximal lateral aspect

of the MtIII or MtIV as an incidental finding that is usually not associated with lameness, although the lesion is scintigraphically active. Splint exostoses can be caused by direct trauma or instability between the metatarsal bones. There is a common misconception that splints arise from tearing of the interosseous ligaments between the MtII or MtIV and the MtIII, but many splints do not involve the space between bones, and it is difficult to believe that instability and primary desmitis adequately explain the cause of splints. Many splints in the hindlimb involve the MtIII alone (and not the MtII or the MtIV), although the MtII and the MtIV can be affected. Axially located exostoses (blind splints) do occur and are most important proximally, where bony proliferation could crowd or impinge on the proximal aspect of the SL and lateral and medial plantar metatarsal nerves. Adhesions may occur between the axial aspect of the exostosis and the SL and other nearby soft tissue structures, but lameness from adhesions and encroachment into the region of the SL appears to involve the McII or McIV most commonly. Direct trauma from interference injury is the most likely cause of most medially located splints. Faulty conformation does not appear to play a prominent role. Mature distal splint exostoses may predispose the MtII and MtIV to fracture in horses with progressive enlargement of the SL.

Lameness associated with splint exostoses is usually mild (grade 1 to 1½ of 5). Direct palpation elicits a painful withdrawal response, and lameness is exacerbated. Infiltration of local anesthetic solution alleviates pain and a majority of observed lameness, but perineural analgesia of the lateral plantar metatarsal and lateral plantar nerves, or medial plantar metatarsal and medial plantar nerves proximal to exostoses involving the MtIV and the MtII, respectively, may be required. Radiographs should be obtained when a fracture is suspected but otherwise yield little useful information unless there is drainage associated with bony proliferation.

Management of horses with splint exostoses includes local cold therapy, including cold water hosing and icing, the application of a poultice and bandaging, and the administration of nonsteroidal antiinflammatory drugs (NSAIDs). Injections of methylprednisolone acetate (80 mg) and Sarapin, an extract of the pitcher plant (6 mL), subcutaneously and axially if needed for each exostosis reduce inflammation and pain. Repeat injections are often necessary. Cryotherapy is popular in racehorses, but clinicians should be aware that superficial skin pain persists for several weeks afterward, which leaves few ways to monitor improvement other than to monitor performance. Surgical removal of persistently painful exostoses by periostectomy, ostectomy of exostoses without removing the parent MtII or MtIV, adhesiolysis, and fasciotomy can be performed if exostoses involve the axial aspects and encroach on or are adhered to the SL. Surgery is usually not required for abaxially located splint exostoses.

Fractures of the Second and Fourth Metatarsal Bones

Fractures of the MtII and MtIV occur primarily as a result of direct trauma from either a kick from another horse or kicking into or through a stationary object. The MtIV is injured most commonly. Simple, comminuted, and

displaced fractures occur, and often wounds extend directly into the fracture site. The MtIV bears little load and appears to have remarkable recuperative ability. Diagnosis is usually straightforward, particularly if a wound is involved, but in some horses the presence of chronic lameness or drainage several weeks after injury prompts later radiographic examination, and only then is fracture diagnosed. Radiographs often reveal extensive comminution, but in many horses, basic axial alignment of fragments is maintained. When fractures of either the MtIV or MtII involve the tarsometatarsal joint, and particularly if fractures are open, infectious arthritis and osteoarthritis are possible but may be amenable to treatment.

The majority of MtIV fractures heal with conservative management, despite comminution and infectious osteitis, with appropriate antimicrobial administration and wound care. Loose subcutaneously located fragments can be removed with ease and deep tissue samples should be collected for bacterial culture and antimicrobial susceptibility testing. Although internal fixation,²² total ostectomy of the MtIV,²³ and segmental ostectomy²⁴ have been described, I have rarely found it necessary to contemplate surgery, with the exception of removing loose bone fragments from wounds or persistently draining tracts (Figure 43-6). Comminuted fractures with an intact column of bone will heal satisfactorily in most horses, although delayed unions or nonunions requiring surgical intervention occur infrequently. Horses may need 4 to 6 months of rest, and long-term antimicrobial therapy (4 to 8 weeks) may be necessary in horses with open or infected fractures. Impingement on

Fig. 43-6 • Dorsal 45° lateral-plantaromedial oblique digital radiographic image of a horse with an open, comminuted fracture of the fourth metatarsal bone (MtIV) (arrows). As long as an intact column of bone is present, fractures of the MtIV will often heal without major surgical intervention except for removal of loose fragments (arrowhead) through the original wound. Long-term management with antimicrobial agents and rest is necessary.

the SL function by callus from fracture healing is a possible complication but is unusual. Fractures of the mid and distal aspects of the MtII and MtIV are caused by chronic suspensory desmitis involving the body or branches. Suspensory desmitis is primary and MtII and MtIV fractures are secondary, resulting from a bowstring effect of the enlarging SL. Occasionally, axially located callus from an old splint bone fracture may cause mild lameness from local irritation of the nearby SL. Local injections of antiinflammatory agents resolve pain in most instances, but occasionally exostoses and the distal aspect of the splint bone are removed.

Ostectomy of distal fragments of the MtII and MtIV can be performed in combination with SL splitting and, in some horses, with ostectomy of apical or abaxial fracture fragments of the PSBs. A triad of clinical problems involving the SL, splint bone, and PSBs (called the *three Ss*) is often seen, and all three structures should be evaluated before management and prognostic recommendations are made.

Enostosis-like Lesions of the Third Metatarsal Bone

During scintigraphic examination, single or multifocal areas of IRU within the medullary cavity of the MtIII are occasionally seen, and intensity can range from mild to intense. Subsequent radiological examination reveals one or more round to irregularly shaped radiopacities within the medullary cavity. Lameness in horses with enostosis-like lesions of the MtIII is unusual, particularly if there are small, focal areas of IRU involving only the area around the nutrient foramen. Of 17 enostosis-like lesions (in 10 horses), four lesions were identified in the MtIII, but in only one horse was lameness localized to the metatarsal region.²⁵ Lameness, if present, should abate with a high plantar block and resolves with rest and the administration of NSAIDs.

Hypertrophic Osteopathy

Hypertrophic osteopathy is discussed in Chapter 37.

Suspensory Desmitis

Suspensory desmitis, including PSD, suspensory body desmitis, and suspensory branch desmitis and associated bony injury, is the most important cause of lameness in the metatarsal region (see Chapter 72).

Hindlimb proximal and proximal and body desmitis are career-threatening injuries and horses should be managed aggressively. Managing horses with hindlimb suspensory desmitis is exceedingly more challenging than managing those with similar forelimb injuries—the proverbial apples and oranges comparison. One of the Editors (SJD) has written extensively on the subject and aptly points out that the prognosis in horses with acute forelimb PSD approaches 90%, whereas prognosis in those with acute hindlimb desmitis managed conservatively is 14%.²⁶ I have managed 23 horses, 13 nonracehorses (dressage horses, jumpers, event horses) and 10 STB trotters, with confirmed proximal and body suspensory desmitis by using autogenous bone marrow injection²⁷ and proximal metatarsal fasciotomy. Horses are placed under general anesthesia, and a medial approach is used to gain access to the proximal aspect of the SL (Figure 43-7). A large volume, 30 to 60 mL, of liquid bone marrow is harvested from the sternum and injected directly into the proximal aspect of the SL and body as determined by ultrasonographic evaluation. The dense,

Fig. 43-7 • An anatomy specimen (A) and a cadaver specimen (B) showing the location and approach (dotted line) for bone marrow injection and fasciotomy used in management of horses with proximal suspensory and body desmitis. Dense metatarsal fascia is being retracted using Allis tissue forceps, exposing the origin of the suspensory ligament (curved Kelly forceps is positioned plantar to the suspensory ligament).

overlying medial metatarsal fascia is transected from the level of just proximal to the tarsometatarsal joint to the midbody region. Although no attempt was made to separately incise the laminar suspensory fascia, this fascial layer is confluent with the overlying metatarsal fascia along the axial aspect of the MtII. The subcutaneous tissues and skin are closed. Horses should be given 4 to 6 months of progressive increase in exercise, including 4 weeks of stall rest, followed by 4 weeks of stall rest with handwalking, 4 weeks

of walking with a rider up or in the jog cart, and then 4 weeks of walking and light trotting. Turnout exercise is forbidden. Of 13 nonracehorses, eight (62%) returned to full work, three of these to elite competition; one horse returned to a lower level of competition, but lameness persisted or recurred in four horses. Of 10 trotters, eight raced but only two raced more than five starts without recurrence of desmitis. Hindlimb suspensory desmitis in the trotter is a substantial cause of lameness and is career-limiting. Whether improvement in some horses may result from reparative processes accelerated by the transfer of stem cells, the injection of growth factor-rich substrate into damaged SLs (see Chapters 72 and 73), fasciotomy and relief of compartment syndrome, or a combination of factors is unknown. In an experimental study, acellular bone marrow was significantly better than platelet-rich plasma and growth factors in stimulating cartilage oligomeric matrix protein production in an *in vitro* study using cultured SL fibroblasts.²⁸ See Chapters 72 and 73 for a complete discussion regarding alternative approaches to healing, reparative and regenerative healing, and other aspects of management of suspensory desmitis. Numerous other management options are available including stem cell therapy (see Chapter 73), a combination of desmoplasty (splitting) and fasciotomy,⁸ fasciotomy and neurectomy of the deep branch of the lateral plantar nerve,⁴ and radial pressure wave therapy.²⁹ Realistically, prognosis is only guarded to fair for return to the same level of competition, particularly in elite horses and STB trotters, and to date, a method of management suitable for all horses is not available. Accurate diagnosis and imaging must be performed to authenticate location and source of pain. Prognosis is particularly guarded in older Warmblood horses with desmitis extending into the body of the SL with palpably thickened metatarsal regions, in those with straight hindlimb conformation and with hyperextension of the metatarsophalangeal joints (dropped fetlock joints), and in those in which desmitis is chronic and recurrent. A particularly severe form of suspensory desmitis is seen in some Warmblood horses, and may possibly be associated with pathological accumulation of proteoglycans in connective tissues, and resembles the degenerative suspensory disorder known to occur in the Peruvian Paso and related breeds.^{30,31} Horses can have severe unilateral or bilateral desmitis with severe lameness and hyperextension of the hock and fetlock joints and are most often refractory to treatment.

Tenosynovitis of the Digital Flexor Tendon Sheath

Tenosynovitis of the DFTS is discussed in Chapter 74.

Desmopathy of the Accessory Ligament of the Deep Digital Flexor Tendon

Desmitis of the ALDDFT is discussed in Chapter 71.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis is discussed in Chapters 70, 76, and 78.

Superficial Digital Flexor Tendonitis

Tendonitis of the superficial digital flexor (SDF) is an unusual-to-rare cause of lameness, but it occurs in racehorses with chronic, progressive curb and in any type of

sports horse as a result of direct trauma (see Chapter 78). SDF tendonitis may be obvious clinically or may be more subtle and requires careful palpation and ultrasonographic examination for confirmation of diagnosis. STB and TB racehorses with spontaneous SDF tendonitis invariably have sickle-hock conformation. The points of the hock should be compared, because in some horses loss of support accompanies SDF tendonitis and is a negative prognostic sign. Long-term rest has been successful in pacers, but trotters and TB racehorses have a poor prognosis for returning to racing. Most horses, regardless of breed or gait, drop in race class.

Undiagnosed Metatarsal Region Lameness

In a small proportion of horses, lameness can be localized to the metatarsal region by high plantar analgesia, but comprehensive imaging fails to identify a source of pain. I believe most of these horses have PSD and pain from subtle swelling of the SL. Measurement of the cross-sectional area and comparison with the contralateral limb are useful. Horses with lameness inappropriate for the degree of injury confirmed using radiographic and ultrasonographic examinations should be referred for scintigraphic examination and are likely candidates for MRI or CT examination. Pain associated with the distal tarsal joints and tarsal sheath occasionally can be abolished using high plantar analgesic techniques, a fact that must be kept in mind in horses in which a diagnosis in the metatarsal region cannot be made.

Wounds of the Metatarsal Region

Wounds involving the metatarsal region are common and can be simple and involve the skin and subcutaneous tissues, but they are often complex and involve bone and deep soft tissue structures. Lacerations often involve the extensor and digital flexor tendons (see Chapter 81), and those involving the digital flexor tendons have serious implications for future performance and salvage. Laceration of the long digital extensor tendon often delays healing of overlying wounds because movement of tendon ends exacerbates granulation tissue formation and delays wound contraction and epithelialization. Horses with long digital extensor tendon lacerations knuckle initially, but functional healing of the tendon most often results. A common wound is a distal-based flap wound that exposes the dorsal cortex of the MtIII and often is associated with extensor tendon lacerations. Because the skin base is distal, much of the proximal, triangular section of skin becomes necrotic. The skin should not be removed prematurely. Osteitis of the MtIII from direct trauma, drying from exposure, superficial infection, and loss of blood supply may prolong healing. Occasionally, large areas of the dorsal cortex of the MtIII have radiological characteristics of sequestra, but in many horses surgical removal or curettage is not required. In my experience, many horses have received unnecessary surgery to remove damaged areas of the MtIII cortex that if left in place would likely have healed uneventfully. However, horses that develop extensive proliferative changes of the MtIII usually have adhesions to the long digital extensor tendon and often have chronic lameness.

Small puncture wounds may result in localized osteitis of the MtII or MtIV. Removal and curettage should be reserved for those with purulent drainage refractory to management with antimicrobial therapy. Horses without

drainage but with radiological evidence of fragmentation within a radiolucent defect can be managed conservatively unless expedient resolution of the problem is mandatory. Horses with wounds and evidence of MtIII cortical crushing or obvious fractures should be managed with caution because catastrophic fracture could develop. Of substantial risk are those with acute, cortical fractures that resemble true saucer fractures. If horses are placed under general anesthesia to remove what is misinterpreted as devitalized pieces of cortex, there is a risk for catastrophic fracture during recovery from general anesthesia.

Acquired or secondary stringhalt is an unusual complication from metatarsal region wounds involving the long digital extensor tendon and sometimes the lateral digital extensor tendon. Horses at risk are those with extensive proliferation of the MtIII and adhesion formation with the overlying long digital extensor tendon. Mechanisms to account for the development of stringhalt include adhesion formation and interruption of the normal myotactic reflex.³² Of 10 horses that developed stringhalt after dorsal metatarsal trauma, six horses developed stringhalt within 3 months, three developed stringhalt after 3 months, and in one horse time of injury to development of stringhalt was undetermined.³² Of four horses managed with rest and progressive exercise, stringhalt resolved in one, improved in two, and remained the same in one horse.³² Of five horses that received surgical management using lateral digital extensor myotectomy, stringhalt resolved in two, improved in two, and remained the same in one

horse.³¹ In my limited experience with this condition, prognosis is guarded to poor for complete resolution of the gait deficit.

Diffuse Swelling in the Metatarsal Region

Diffuse swelling in the metacarpal region is discussed in Chapter 37, and this also applies to the metatarsal region.

Severe Cellulitis of the Metatarsal Region

Cellulitis of the hindlimb occurs frequently from kick wounds or other trauma. In many horses obvious signs of trauma are lacking, but severe lameness and signs of infection in the metatarsal region occur. A severe form of cellulitis occurs primarily in TB racehorses in which severe lameness, swelling, and fever develop, apparently from a very small skin wound or excoriation, because an obvious wound is most difficult to find. This condition is similar to focal, peritarsal cellulitis (see Chapters 44 and 107). Initially it is difficult to differentiate cellulitis from infection of the tarsal sheath, SDFT, DDFT, and the DFTS, because swelling is diffuse and horses are severely lame. Within 48 to 72 hours, skin necrosis and sloughing can occur, which exposes an underlying and sometimes infected SDFT. *Staphylococcus* and occasionally *Streptococcus* species are cultured. Laminitis in the contralateral limb is a risk initially. Skin sloughing can be pronounced and requires weeks to months of wound care and, in some horses, grafting. Involvement of the underlying SDFT and other soft tissue structures is a poor prognostic sign.

Chapter 44

The Tarsus

Sue J. Dyson and Mike W. Ross*

ANATOMICAL CONSIDERATIONS

The tarsus consists of the tarsocrural, talocalcaneal, talocalcaneal-centroquartal (proximal intertarsal), centrodistal (distal intertarsal), and tarsometatarsal joints. The bones include the talus and calcaneus and the central, first and second fused, third, and fourth tarsal bones.¹ The tarsocrural joint is a ginglymus joint based on the shape of deep grooves on the cochlear articular surface of the distal end of the tibia with the extensive surface of the trochlea of the talus. The articulation of these joints is at an angle of 12 to 15 degrees dorsolateral to the sagittal plane of the limb. The talocalcaneal-centroquartal (proximal intertarsal), centrodistal, and tarsometatarsal joints are plane joints and are capable of only small amounts of gliding (shear) movement.

The tibia follows an almost circular path along the talar ridges, and most movement occurs in the tarsocrural joint; however, there are translations and rotations at other sites.² Hock flexion is associated with abduction of the distal part of the limb caused by an oblique axis of motion.³ There is outward rotation of the third metatarsal bone (MtIII) during the swing phase, followed by a small inward rotation during stance, when the hock is compressed. Thus at the gallop the hindlimbs swing outside the forelimbs as the tarsus flexes and then move back toward the midline as the tarsus extends before landing. Excessive rotation leads to visible wobbling of the tarsus. There is a locking mechanism among the talus, the central and third tarsal bones, and the MtIII.⁴ A process on the distal plantar aspect of the talus fits into an indentation on the proximal aspect of the central tarsal bone; a ridge on the distal aspect of the central tarsal bone engages with a fossa on the proximal aspect of the third tarsal bone. A triangular plantar process of the third tarsal bone prevents the third tarsal bone from sliding across the proximal aspect of the MtIII. The oblique dorsal ligament extends distally from a small origin on the talus, spreading across the central and third tarsal bones, limiting motion.

Biomechanical studies have shown greatest compression on the distal medial aspect of the tibia and the proximal lateral aspect of the MtIII, suggesting that compressive load is transferred from medial to lateral through the tarsus. Radiopharmaceutical uptake (RU) in normal horses is greatest dorsally and laterally in the distal aspect of the

*The authors acknowledge and appreciate the work of Robin M. Dabareiner and G. Kent Carter, who contributed to this chapter in the previous edition of this text.

tarsus, suggesting increased adaptive bone modeling in response to high load.⁵ There are differences in subchondral bone and cartilage thickness in the central and third tarsal bones from medially to laterally, varying dependent on intensity and type of exercise history, reflecting loading.^{6,7} The distal tarsal joints function to absorb energy in the early stance phase and contribute to propulsion in the late stance phase. Conformation influences tarsal function.⁸ Horses with large tarsal angles (>165.5 degrees) have been shown to have less flexion and less energy absorption in the impact phase at the trot compared with horses with intermediate (155.5 to 165.5 degrees) or small (<155.5 degrees) angles.⁸ Horses with large hock angles generated less vertical impulse than horses with small angles, and net extensor force was lower.⁸ Thus large tarsal angles may result in less propulsion and less absorption of concussion, which may influence both performance and soundness. However, horses with small hock angles had greater flexion during the stance phase, which may compress the dorsal aspects of the bones. Abnormal tarsal conformation can lead to lameness. Anecdotally, horses with small hock angles (sickle hocks) often develop osteoarthritis (OA) of the distal hock joints, curb, and soft tissue injury in the distal, plantar aspect of the hock and may be prone to the development of fracture of the central and third tarsal bones. Horses with large hock angles (straight-hock conformation), surprisingly, may be less prone to the development of tarsal pain, but they appear predisposed to the development of suspensory desmitis and stifle region pain.

Flexion of the stifle and hock is synchronous because of the reciprocal apparatus; there is rapid flexion of the tarsus at the beginning of the stance phase of the stride and maximal extension at the end of the stance phase. There is a peak of flexion in the middle of the swing phase. There is also coupling of movement of the tarsus and fetlock in flexion and extension because of passive action of the superficial digital flexor tendon and the long digital extensor tendon, respectively.

The fibrous part of the combined tarsal joint capsule surrounds all synovial compartments and attaches proximally to the tibia and distally to the distal tarsal bones, blending with the collateral ligaments (CLs), and to the metatarsal bones.² The dorsomedial aspect of the joint capsule is thin and uncovered by any tendons or ligaments and forms a fluctuant swelling over the medial trochlea of the talus. The proximal aspect of the plantar fibrous joint capsule is also thin and extends proximally about 5 cm caudal to the distal aspect of the tibia.² The plantar distal aspect of the joint capsule consists of the plantar and tarsometatarsal ligaments, which are thick and tightly adherent to the distal tarsal bones. The tarsus is composed of four synovial compartments. The tarsocrural compartment lubricates the tarsocrural joint and the dorsal aspect of the proximal intertarsal joint. The tarsocrural compartment is the largest compartment and is composed of four pouches: the dorsomedial, dorsolateral, plantaromedial, and plantarolateral. This provides several sites at which arthrocentesis can be performed. The proximal intertarsal synovial sac lines the talus and calcaneus proximally and the plantar aspect of the central and third tarsal bones distally and communicates dorsally with the tarsocrural joint. The large fenestration between the tarsocrural and the proximal intertarsal joints allows loose osteochondral fragments to

move freely between the conjoined joints. Disease of one joint obligatorily involves both compartments, because they function as one. In horses <1 year of age this opening appears small or slitlike or is not readily apparent when evaluated arthroscopically. The centrodistal joint lubricates the articulation between the central and third tarsal bones and the bones on each side, and the tarsometatarsal joint lubricates the third and fourth tarsal bones with the second metatarsal bone (MtII), the MtIII, and the fourth metatarsal bone (MtIV). The superficial location of the joint capsules makes them susceptible to penetration and the introduction of infection in association with trauma to the tarsus.

There is communication in 8% to 39% of the centrodistal and tarsometatarsal joints, but not necessarily in both hocks of the same horse,⁹⁻¹¹ although substances may spread between them by diffusion even in the absence of frank communication.^{12,13} Communication between the distal tarsal joints and the tarsocrural joint was demonstrated in 3% of horses after injection of radiodense contrast medium into the tarsometatarsal joints in live horses¹⁰; however, in a cadaver study mepivacaine injected into the centrodistal or tarsometatarsal joints spread to the tarsocrural joint within 15 minutes of injection in 88% and 92% of limbs, respectively.¹²

Anatomical aspects of the gastrocnemius and calcaneal bursae and the tarsal sheath are discussed elsewhere (Chapters 76, 79, and 80). The distal tendon of the long digital extensor muscle is enclosed within a synovial sheath as it passes over the dorsolateral aspect of the tarsus. This sheath is compressed by transverse retinacular bands, resulting in a loculated appearance if the sheath is distended. Such longitudinal swelling is a quite common incidental finding in both sound and lame horses either unilaterally or bilaterally and is only rarely associated with pain and lameness. Focal lesions of the long digital extensor tendon have been identified ultrasonographically, but usually unassociated with lameness.

Numerous ligaments surround the hock. Both the lateral and medial CLs have one long and three short components.¹⁴ The long lateral CL is superficial; originates at the caudal aspect of the lateral malleolus of the distal tibia; inserts on the distal lateral aspect of the calcaneus with additional fibers to the fourth tarsal bone, the MtIII, and the MtIV; and forms a canal for the tendon of the lateral digital extensor muscle. The short lateral CLs lie deep to the long lateral CL and originate from the cranial aspect of the lateral malleolus, pass plantad, and attach to the lateral surface of the calcaneus and the proximolateral plantar aspect of the talus. The long medial CL originates from the caudal aspect of the medial malleolus, attaches distally to the MtII and the MtIII, and also attaches to the medial aspect of the distal tarsal bones. The short medial CLs lie deep to the long medial CL and extend from the medial malleolus to the medial aspect of the calcaneus and sustentaculum tali. The long plantar ligament is a strong, flat band that originates at the proximal plantar surface of the calcaneus, extends distally, and attaches to the fourth tarsal bone and the MtIV. The dorsal tarsal ligament spreads out distally from the distal tuberosity of the talus and attaches to the central and third tarsal bones and proximal aspect of the MtIII and the MtIV. Numerous short intertarsal ligaments connect adjacent bones of the tarsus and have connections between tarsal and metatarsal bones.

The suspensory ligament (SL) also has an accessory ligament that extends proximally to originate from the plantar aspect of the fourth tarsal bone and the calcaneus.¹⁵ This anatomical relationship between the SL and the tarsus may explain why distal hock joint pain and suspensory injury may coexist, why some horses with primary SL pain show a positive response to tarsal flexion, and why there may be confusion with diagnostic analgesic techniques used to differentiate distal hock joint pain from proximal suspensory desmitis.

Diagnosis

Clinical Signs

Swelling is a variable feature of hock-related lameness. There are numerous common swellings of the tarsus, but the presence of swelling is not pathognomonic for tarsal region pain (see Chapter 6, page 58, and Figures 6-28 through 6-32). Swellings include capped hock, which must be differentiated from lateral dislocation or luxation of the superficial digital flexor tendon and swelling of the calcaneal bursae; tarsal sheath-associated or, less commonly, non-sheath associated thoroughpin; bog spavin (effusion of the tarsocrural joint); bone spavin (bony prominence of the dorsal and medial aspects of the distal tarsal region); curb (see Figure 78-1), a collection of soft tissue injuries involving the distal plantar aspect of the hock; and diffuse soft tissue swelling in the distal aspect of the crus and dorsal aspect of the tarsus associated with injury of the fibularis (peroneus) tertius. Rapid development of diffuse periarticular swelling may follow trauma of the tarsus or may herald periarticular cellulitis. Distention of the tarsocrural joint can be an incidental finding but may reflect primary joint pathology. Distention of the distal hock joint capsules is rarely detectable clinically, but if it occurs in association with OA, there may be firm enlargement on the medial aspect of the limb reflecting periarticular new bone and overlying fibrous tissue. The presence of this swelling, bone spavin, is neither required for horses to be lame as a result of distal hock joint pain nor pathognomonic for distal hock joint pain in horses in which it is found. Swelling restricted to the medial or lateral aspect of the tarsus may reflect CL injury and malleolar fractures of the distal aspect of the tibia.

Some horses with tarsal region pain resent passive flexion, but exaggerated lifting of the limb to avoid maximal flexion is more likely to reflect stifle pain. Although there are many advocates of the Churchill test for the detection of distal hock joint pain (see Chapter 6), we do not find this test particularly useful because there are many false-positive and some false-negative responses. This may reflect the degree of pressure applied, because one author (SJD) is rarely able to induce pain, whereas the other (MWR) frequently does elicit a pain response. Some horses with distal hock joint pain do manifest a positive reaction to palpation of the medial soft tissue structures and the proximal medial metatarsal region, likely reflecting the presence of periarticular soft tissue pain associated with OA. Horses often manifest a positive response to compression of the distal medial aspect of the tarsus and proximal medial aspect of the metatarsal region statically, and lameness can often be exacerbated with compression of this region followed by trotting, a dynamic test; yet pain in these horses is localized

with diagnostic analgesia to the distal portion of the hindlimb. Proximal suspensory desmitis and lameness associated with the metatarsophalangeal joint are common diagnoses in these horses. It is possible that horses with distal hindlimb pain move abnormally and have coexistent pain in the region compressed using the Churchill test (see Figures 6-33 through 6-35). The absence of a positive Churchill test result should not lead the examiner to conclude the horse does not have tarsal region pain, a false-negative response. Unless clinical signs are diagnostic or a horse is suspected to have a fracture, diagnostic analgesia should always be used to confirm the presence of tarsal region pain.

Shoe wear can be excessive in horses with chronic tarsal region pain. Shoes are often worn on the toe or, most commonly, on the dorsal and lateral aspects (see Figure 6-38). Often, the fullering and toe grab, if present, are worn completely through, a finding that is most prominent in horses shod in aluminum shoes. Horses with pain causing lameness from other sources in the distal aspect of the hindlimb can manifest similar shoe wear, so this finding is not pathognomonic of distal hock joint pain. Horses with chronic tarsal region pain often have coexistent signs of pain on palpation of the gluteal and thoracolumbar area. Concurrent back and gluteal pain is likely secondary to chronic abnormal limb carriage causing muscle pain.

Lameness can range from mild to severe. Horses often warm out of lameness and are often able to perform with low-level distal hock joint pain. In racehorses, particularly the Standardbred (STB), trainers often comment that the “horse throws away the lameness at speed.” There are no pathognomonic clinical signs or gait deficits associated with tarsal region pain. Gait abnormalities associated with hock-related lameness are very variable both in degree and in character, depending on the underlying cause of lameness. A reduction in the cranial phase of the stride at the trot is a consistent finding but is a common finding in horses with any source of pain causing hindlimb lameness. When observed from behind, a trotting horse with tarsal region pain during protraction swings the affected hindlimb medially toward the midline and then stabs laterally while landing, often called a “stabby” hindlimb gait. This is particularly noticeable when horses have bilateral hindlimb lameness. Based on the clinical observation of a stabby hindlimb gait and positive response to upper limb flexion (see later) a diagnosis of distal hock joint pain is made, particularly in Western performance horses or gaited breeds, and empirical treatment is undertaken and is successful. However, this stabby hindlimb gait is not pathognomonic for tarsal region pain, and horses with lameness as a result of pain originating anywhere in the distal aspect of the hindlimbs can manifest this type of gait abnormality. Diagnostic analgesia should be used if horses do not respond to initial treatment. Some horses with severe tarsal region pain and swelling carry the limb wide, avoid flexion, and swing the limb laterally during protraction. These horses are often reluctant to flex the hock while standing during the palpation and manipulation portions of a lameness examination.

Kinematic gait measurements were recorded after endotoxin-induced lameness of the distal tarsal joints.¹⁶ Both fetlock and tarsal joint extension during stance phase decreased, fetlock joint flexion and hoof height during swing phase increased, limb protraction decreased, and

vertical excursion of the tuber coxae became more asymmetrical. These observations are not entirely consistent with the observations made in natural disease.

More recently, three-dimensional kinematic gait analysis was performed before and after experimental induction of synovitis of the centrodistal and tarsometatarsal joints resulting in mild lameness.¹⁷ There were significant decreases in tarsal joint flexion and in dorsal translation (sliding) of the metatarsal region relative to the tibia during the stance phase.¹⁷ Measurement of ground reaction forces with subtle lameness indicated reduced weight bearing on both the lame hindlimb and the contralateral forelimb but no change in the opposite hindlimb. Thus the gait may appear to have less bounce, rather than overt lameness being detectable. With mild increase in lameness there was reduced tarsal flexion in the stance phase and decreased forward sliding of the distal joints. This results in reduced propulsion, influencing quality of the gait, and less absorption of concussion. Movements that require maximum tarsal flexion are likely to be most painful, and resistance to perform such movements may be apparent before lameness is observed.

Horses with tarsal region pain often respond positively to an upper limb flexion test (see Chapter 8, page 84 and Figure 8-8). This test has erroneously been called the *spavin test* and a positive response should not be interpreted as pathognomonic for tarsal region pain. When it is suspected that a horse has tarsal region pain, this test often gives false-positive results. The most marked response to an upper limb flexion test may indeed be observed in horses with tarsal region pain, but a positive response can be seen with pain originating from the stifle, the hip region, and even the distal aspects of the limb. The upper limb flexion test is not specific, nor is the “hock extension test” (see Figure 8-10), a test used to exacerbate lameness in horses with tarsal region pain. There is no substitute for accurate diagnostic analgesia.

Diagnostic Analgesia

Analgesia of the hock region can be accomplished by perineural analgesia of the fibular (peroneal) and tibial nerves or by intraarticular analgesia. Although the latter is theoretically more specific, there are a number of important limitations. False negative results can occur in the presence of subchondral bone pain and/or extensive cartilage pathology. Horses with incomplete fractures of the talus or central tarsal bone often show little response to intraarticular diagnostic analgesia but do show a marked improvement after perineural analgesia of the fibular and tibial nerves. Lameness may be improved rather than abolished, and although this may be easy to appreciate in a moderately lame horse, it is less easy in a horse with a subtle lameness. Intraarticular analgesia has limited ability to influence periarticular soft tissue structures that may be contributing to pain causing lameness. The capacity of the centrodistal and tarsometatarsal joints is relatively small, and injection of too large a volume of local anesthetic solution results in leakage; the close proximity of the plantar outpouchings of the tarsometatarsal joint to the SL means that intraarticular analgesia of the tarsometatarsal joint may remove pain from the SL. With advanced joint space loss or periarticular new bone formation, intraarticular analgesia may not be physically possible.

Perineural analgesia of the fibular and tibial nerves is well tolerated by most horses (see Chapter 10). One of us (SJD) deposits a subcutaneous bleb of local anesthetic solution at both injection sites using a 25-G needle before performing the blocks. Although a 3.7-cm needle is adequate for most horses, to reach the deep branch of the fibular nerve requires a 5-cm needle in large (700 kg) horses. These nerves are large, and it takes longer for analgesia to develop than with more distal limb blocks. Do not be in a hurry to move proximally in the limb and perform intraarticular analgesia of the stifle or hip joints, because these blocks may take a full hour to work. We usually first evaluate the horse 20 minutes after injection and for up to an hour. It is important to recognize that successful blocks may increase or create a toe drag; improved stride length, rhythm, and symmetry of the hindquarters must therefore be used to evaluate improvement in lameness. Occasionally a horse will stumble slightly after fibular and tibial nerve blocks, but we commonly see horses ridden before and after and do not believe there are undue risks.

When performing intraarticular analgesia of the distal tarsal joints, we routinely block the tarsometatarsal joint first, because this is relatively easy and safe to perform, and commonly find that horses with centrodistal joint pathology are improved. If there is partial or no response, then the centrodistal joint is blocked. In a study using 66 cadaver limbs, mepivacaine (5 mL) was injected into either the tarsometatarsal or centrodistal joints; synovial fluid samples were collected from the tarsocrural, centrodistal, and tarsometatarsal joints 15 minutes later.¹² Concentrations of mepivacaine that were potentially analgesic were found in the centrodistal and tarsocrural joints after injection of the tarsometatarsal joint in 64% and 4% of limbs, respectively. After injection of the centrodistal joint, analgesic concentrations of mepivacaine were found in the tarsometatarsal and tarsocrural joints in 60% and 24% of limbs, respectively. Despite these results we have never clinically recognized improvement in tarsocrural joint pain after intraarticular analgesia of the centrodistal and/or tarsometatarsal joints. We use a maximum volume of 3 to 4 mL of mepivacaine and evaluate the response 5 to 10 minutes after injection. Larger volumes will leak out of the injection site, increasing the likelihood of inadvertent analgesia of the proximal SL and other metatarsal structures. False-negative results may occur even in the absence of detectable radiological abnormalities, and the response to intraarticular medication may be substantially better. However for the much larger tarsocrural joint we use at least 20 mL of mepivacaine and will wait up to 30 minutes before declaring that the response is negative. One of us (MWR) has found that volumes of local anesthetic solution of up to 40 to 50 mL may be required to abolish pain associated with severe OA of the tarsocrural joint, and often the examiner needs to wait 45 to 60 minutes for the full effect of the intraarticular block to work.

DIAGNOSTIC IMAGING

Four radiographic images of the tarsus are required: lateromedial, dorsolateral-plantaromedial oblique, dorsomedial-plantarolateral oblique (DM-PILO), and dorsoplantar.¹⁸ Lesions may be detectable only in a single view; thus in our opinion all four views should be obtained routinely.

To cut through the centrodistal and tarsometatarsal joint spaces, it is important that the horse be standing with the metatarsal region vertical and bearing weight evenly on each hindlimb. Because the centrodistal and tarsometatarsal joints slope distally from laterally to medially, to reliably cut through the joint spaces in a lateromedial image, the x-ray beam should be angled 10 degrees distally. If a horizontal x-ray beam is used, it can be difficult to cut through the entire centrodistal joint space in a dorso-plantar projection, and it may appear that one side of the joint is narrowed. An additional dorsal 5° proximal-plantarodistal oblique image helps to determine whether there is genuine joint space narrowing.

Some lesions may be missed in dorsoplantar images, such as an axial osteochondrosis lesion of the medial malleolus of the tibia or a parasagittal fracture of the talus. Additional views obtained by angling the x-ray beam slightly obliquely (dorsal 10- to 20° lateral-plantaromedial oblique image) may be required in selected horses. A flexed lateromedial image and a flexed skyline image can give important additional information in some horses, particularly those with lesions involving the proximal and plantar aspects of the talus, those with osteochondral fragments involving the plantar pouch of the tarsocrural joint, and those with radiolucent defects on the calcaneus. A flexed dorsoplantar image can be useful to evaluate the proximal aspect of the talus in horses with incomplete fractures of this bone but is difficult to obtain.

Nuclear scintigraphy is most useful when pain causing lameness has been localized to the tarsus but no radiological or ultrasonographic abnormalities are detected to explain the lameness.¹⁹ The identification of increased radiopharmaceutical uptake (IRU) may prompt acquisition of additional radiographic images that yield a diagnosis. Scintigraphy may also be useful in horses that are difficult to nerve block or those that are examined for poor performance rather than overt lameness. It is important to recognize that RU in the distal tarsal bones can be influenced by the type of work history. For example, there is greater RU in the dorsal aspect of the central and third tarsal bones in elite show jumpers compared with horses from other disciplines.⁵ In a plantar scintigraphic image of the tarsus it is common and considered normal to have greater RU in the subchondral bone of the lateral aspect of the tarsometatarsal joint and the proximal aspect of the MtIV compared with medially.²⁰ This finding should not be interpreted as supportive of a diagnosis of distal hock joint pain. In young racehorses with early OA of the centrodistal and tarsometatarsal joints, focal moderate-to-intense IRU is found most often in the dorsal and lateral aspects of these joints, corresponding to radiological abnormalities detectable on the dorsomedial-plantarolateral radiographic image.²¹ The most common location for fractures of the central and third tarsal bones is on the dorsolateral aspect, and fractures can most reliably be seen in the dorsomedial-plantarolateral oblique radiographic image (Figure 44-1). These findings differ somewhat from most anecdotal reports, suggesting that it is the medial aspect of these joints that show early radiological changes and may be a reflection of a difference between racehorses and sports horses. In older racehorses with advanced OA and sports horses, scintigraphic and radiological evidence of OA is commonly found on both the medial and lateral aspects of the distal hock joints.

Fig. 44-1 • A, Lateral (left two images) and plantar scintigraphic images of a 2-year-old Standardbred pacing filly with right hindlimb lameness as a result of a central tarsal bone fracture. Focal, moderate increased radiopharmaceutical uptake can be seen involving the dorsolateral aspect of this bone (arrows), a common location to find fractures or early osteoarthritis in racehorses. **B,** Dorsomedial-plantarolateral (DM-PILO) digital radiographic image showing an incomplete fracture of the central tarsal bone (arrows). Fractures of the central and third tarsal bones and early signs of osteoarthritis can be seen most commonly in a DM-PILO radiographic view, indicating disease in young racehorses is found in predominantly the dorsal and lateral aspects of the distal hock joints.

Ultrasonography is invaluable for the assessment of both periarticular soft tissues and the tarsocrural joint. An excellent review of normal anatomy and examples of abnormality are published elsewhere.²² Magnetic resonance imaging (MRI) and computed tomography (CT) have the potential to yield valuable additional information when a diagnosis cannot be reached by other means. Normal MRI and CT anatomy references are available.²³⁻²⁵

ARTICULAR DISEASES OF THE TARSUS

Osteoarthritis of the Distal Hock Joints and Distal Hock Joint Pain

Distal hock joint pain is common in horses from all disciplines and is often associated with OA. Distal hock joint pain is known colloquially as *bone* or *jack spavin* or *occult*

or *blind spavin* in the absence of radiological abnormalities. The term *juvenile spavin* has been used to describe early OA that had a prevalence of 20% in a group of horses younger than 2 years of age.²⁶ Although it is usually seen in mature horses used for sport or pleasure, distal hock joint pain can occur in young Thoroughbred (TB) and STB racehorses and Western performance horses (see Chapter 120). Distal hock joint pain may be a sequela to incomplete ossification of the central and third tarsal bones (see page 517). Certain conformational abnormalities (such as sickle-hock, in-at-the-hock, or cow-hock conformation) or excessive straightness of the hindlimbs may predispose to distal hock joint pain, although this condition frequently occurs in normally conformed horses. Traditionally it has been proposed that OA of the distal hock joints is caused by excessive compression and rotation of the distal tarsal joints as the horse jumps or stops, which results in abnormal tension on the intertarsal ligaments. However, this theory is not consistent with the common recognition of distal hock joint pain in pleasure horses or its high incidence in Icelandic horses, a breed in which OA is thought to be a heritable condition.²⁷ Distal hock joint pain is classically thought to begin on the dorsomedial aspect of the joints and to progress dorsally. However, it is our experience that in OA, scintigraphic or radiological abnormalities are frequently first identified only on the dorsolateral aspect of the joints, a region of high compressive strain. Previous exercise history and thus loading of the joints may be influential.²⁸ Nuclear scintigraphic studies of clinically normal mature horses in active work has shown mild greater uptake of radiopharmaceutical on the lateral aspect, which is consistent with increased modeling, presumably the result of a relative increased loading laterally compared with medially.⁷

The centrodistal and tarsometatarsal joints are most commonly affected, either individually or together, but OA of the proximal intertarsal joint does occur, usually in association with OA of the more distal joints. The condition may be unilateral but is often bilateral. Occasionally OA of the talocalcaneal joint occurs either in isolation^{29,30} or together with OA of the centrodistal and tarsometatarsal joints³¹ (see page 516).

History

Clinical signs of distal hock joint pain vary considerably among horses, ranging from a moderate-to-severe unilateral lameness to subtle changes in performance without overt lameness (see Chapters 97 and 106 to 129). These signs include the horse becoming disunited in canter, being unwilling to canter with a particular lead, and being reluctant to turn or decelerate with proper engagement of the hindlimbs. The owner may comment that the farrier has experienced difficulties when shoeing the horse. Frequently a horse with bilateral distal hock joint pain has low-grade stiffness that wears off (warms out of pain) with work. Lameness frequently improves or resolves with rest but recurs when work is resumed. Treatment with nonsteroidal antiinflammatory drugs (NSAIDs) usually results in an improvement in lameness unless it is severe.

Clinical Signs

In many horses no abnormalities are detectable by visual inspection or palpation of the hock region. In horses with more chronic distal hock joint pain there may be

enlargement over the medial or dorsomedial aspects of the distal hock joints, which is the result of periarticular soft tissue thickening. Distention of the tarsocrural joint capsule may occur either coincidentally or reflect involvement of the proximal intertarsal joint. Frequently there is secondary soreness of the epaxial muscles in the lumbar region and sometimes caudal gluteal muscle soreness. The toe and branches of the shoe of the lame limb, or both limbs, may wear abnormally. In our experience, shoe wear in this location, however, is not pathognomonic of distal hock joint pain. Some horses, if not properly trimmed, develop lateral flare of the hoof and mediolateral foot imbalance, with the foot higher medially. Lameness may worsen when shoe additives such as toe grabs and heel calks are applied, an observation that can be useful in therapeutically shoeing a horse with distal hock joint pain (see later). Flexion of the limb may be resisted slightly, but marked lifting of the limb during flexion is more likely to reflect stifle pain. The Churchill test (see Chapter 6) is helpful in identifying distal hock joint pain in some, but by no means all, horses. Soreness associated with specific acupuncture points (see Chapter 92) can also be suggestive of distal hock joint pain.

Lameness varies greatly in degree and is not necessarily correlated with the degree or type of osteoarthritic change detected radiologically. The horse should be assessed moving from the side, from behind, and from in front to appreciate all gait abnormalities. These abnormalities may include asymmetrical movement of the tubera coxae and tubera sacrale; reduced arc height of foot flight, with or without toe drag; shortening of the cranial phase of the stride; reduced extension of the fetlock; and a tendency for the limb to swing medially during protraction and slide laterally at ground contact. Lameness may be accentuated on a circle, in some horses with the lame or lamer limb on the outside, and in others with it on the inside. Gait abnormalities may be accentuated if the horse is ridden. However, none of these characteristics is pathognomonic for distal hock joint pain.

Proximal (upper) limb flexion tests (i.e., the so-called *spavin test*) are useful in accentuating lameness in some, but not all, horses with distal hock joint pain. The hindlimb should be held with the metatarsal region parallel to the ground for 60 to 90 seconds before the horse is trotted away. The limb may be held either by the toe of the foot or by cupping the hands behind the fetlock. Applying pressure to the digital flexor tendons should be avoided. The response to flexion should be interpreted in light of the discipline of the horse, current work history, the degree of accentuation of lameness, and its duration. Flexion of the nonlame or least lame limb should be performed first and the response compared with the contralateral limb. In some horses there is a paradoxical increase in lameness in the weight-bearing limb, presumably because of joint compression or increased subchondral bone pressure. Because of the reciprocal apparatus of the hindlimb, a positive response to proximal limb flexion is not specific for distal hock joint pain. The response to flexion may be recorded as none (0), mild (+1), moderate (+2), or severe (+3). A severe response is unusual in horses with distal hock joint pain.

Diagnostic Analgesia

Diagnostic analgesia is important to confirm the source(s) of pain. Although intraarticular analgesia is potentially

Fig. 44-2 • **A**, Dorsolateral-plantaromedial oblique radiographic image of the tarsus of a horse with mild periarticular osteophyte formation (*arrow*) on the distal dorsomedial aspect of the central tarsal bone and increased radiopacity of the adjacent trabecular bone. **B**, Lateromedial radiographic image of the distal tarsal joints. There is a large periarticular osteophyte on the dorsoproximal aspect of the third metatarsal bone (*arrow*), traversing the tarsometatarsal joint.

more specific than perineural analgesia, the results can be misleading. A negative response to intraarticular analgesia does not preclude distal hock joint pain. Narrowing of the centrodistal joint space or periarticular new bone can prohibit intraarticular injection. In the presence of extensive subchondral bone damage the response to intraarticular analgesia is very poor. Even in the absence of radiological change the response to intraarticular medication is sometimes substantially better than that to intraarticular analgesia, but the converse is also true in some horses.

However, intraarticular analgesia is very useful in many horses. The degree of communication between the centrodistal and tarsometatarsal joints is variable.^{9,10} The techniques for intraarticular analgesia are described in Chapter 10. Improvement in lameness by 50% or more is considered a positive response. In our experience, lameness is often substantially improved within 10 minutes, although some practitioners reassess lameness after 30 minutes.³² We find reassessment of the response to flexion potentially misleading, although some practitioners routinely repeat flexion tests.³² Perineural analgesia of the superficial and deep fibular (peroneal) and tibial nerves (see Chapter 10), although not specific for distal hock joint pain, can be very helpful in confirming hock pain, assuming that pain arising from the more distal aspects of the limb has already been excluded. With practice these blocks are reliable and safe and often result in a much greater degree of improvement in lameness than intraarticular analgesia. Improvement is generally seen within 20 minutes, but occasionally the response is delayed, and it is preferable not to proceed with further blocks until at least 1 hour has elapsed. Horses with specific performance problems associated with distal hock joint pain, rather than overt lameness, may respond better to intraarticular medication than either intraarticular or perineural analgesia.

Radiography and Radiology

Both hocks should be examined radiographically because the condition is often bilateral, although at the time of examination lameness may be unilateral. Radiological abnormalities consistent with osteoarthritis include periarticular osteophyte formation (Figure 44-2), subchondral

Fig. 44-3 • Dorsolateral-plantaromedial oblique radiographic image of the tarsus of a horse with osteoarthritis of the centrodistal joint. There is subchondral radiolucency involving the subchondral bone of the medial aspect of the centrodistal joint (*arrow*). There is also increased opacity in the region of the interosseous ligament between the central and third tarsal bones.

lucent areas (Figure 44-3), increased opacity of subchondral and trabecular bone, periosteal new bone, and narrowing of joint spaces. The correlation between the degree of lameness and the extent of radiological abnormalities is poor.^{33,34} Some horses show profound lameness initially, with no detectable radiological abnormality but with rapidly progressive lesions. Other horses respond to intraarticular analgesia but never develop radiological abnormalities. However, extensive changes may be present when lameness is first recognized. Some horses predominantly develop periarticular changes, whereas others have abnormalities confined to the central and third tarsal bones and the proximal aspect of the MtIII. The reason for these differences is currently unclear. Small osteophytes or enthesophytes on

the dorsoproximal aspect of the MtIII can be incidental radiological abnormalities; they were found to occur in 25% of 455 horses, in 13% of which they were bilateral.³⁵ Osteophytes and enthesophytes could not be reliably distinguished. There was no significant difference in frequency of occurrence in lame and nonlame horses; nor was there any significant difference in frequency of occurrence among horses with distal hock joint pain, proximal suspensory desmitis, or other causes of lameness unassociated with the hock.³⁵ However, there was an association between the presence of a spur and the radiological grade of OA in the centrodistal and tarsometatarsal joints. Horses with severe subchondral radiolucency tend to be lamers and respond poorly to intraarticular analgesia and intraarticular medication. Involvement of the talocalcaneal-centroquartal (proximal intertarsal) joint merits a more guarded prognosis.

Nuclear Scintigraphy

In many horses nuclear scintigraphy is unnecessary, but it can be very helpful in difficult horses and those with performance problems rather than overt lameness.^{19,36} A region of IRU may be focal or more diffuse. Very focal IRU may reflect intertarsal ligament enthesopathy rather than OA.³⁷ Intense IRU may be present in the absence of radiological abnormality, and these horses tend to respond poorly to intraarticular medication, despite a positive response to intraarticular analgesia. In young racehorses and in some sports horses, focal IRU can indicate the presence of a fracture of the central or third tarsal bone (see Figure 44-1), explaining the lack of response to intraarticular medication. Because IRU may occur in association with primary lameness originating from pain elsewhere in the limb, results should be interpreted cautiously, unless supported by radiological abnormalities.

Treatment

The aim of treatment is to provide pain relief so that the horse can remain in work. Traditionally it has been suggested that if the horse is maintained in work, the affected joints will fuse. However, progressive radiological ankylosis is rarely observed, although radiological examination tends to underestimate the degree of joint fusion. Horses with involvement of the talocalcaneal-centroquartal joint and extensive radiolucent defects of subchondral bone have a more guarded prognosis.

Treatment options include a combination of palliative therapy with NSAIDs; intraarticular medication with corticosteroids, hyaluronan, or polysulfated glycosaminoglycans (PSGAGs); with or without systemic treatment with PSGAGs, oral nutraceuticals, or both, combined with corrective trimming and shoeing³⁸; and adaptation of the work program. Extracorporeal shock wave treatment has recently been described, but long-term results are lacking.³⁹ Intravenous infusion of a bisphosphonate, tiludronate, may reduce the severity of lameness in some horses but rarely results in resolution of lameness.⁴⁰ If medical therapy fails, surgical treatment, including cunean tenectomy, subchondral forage to reduce intraosseous pressure,⁴¹ drilling of the affected joints to promote arthrodesis,⁴² chemical induction of ankylosis using sodium monoiodoacetate⁴³⁻⁵¹ or ethyl alcohol,⁴⁶ and neurectomy⁴⁷ are options.

Selection of treatment depends on the degree of lameness, extent of radiological abnormalities, use of the horse,

regulations for competition, response to previous treatment, time available, and financial constraints. Resting the horse usually is not beneficial. Palliative treatment with NSAIDs such as phenylbutazone is useful in pleasure horses; the lowest dose that alleviates lameness should be used. Long-term use of phenylbutazone, 1 g twice daily for a 500-kg horse, is generally well tolerated. Any treatment should be combined with corrective trimming and shoeing to ensure correct mediolateral balance and to facilitate breakover by shortening the toe, squaring and rolling the toe of the shoe, or setting the shoe back from the toe. A lateral trailer¹⁴ or a lateral extension of the shoe provides symptomatic relief in some horses and tends to stop excessive twisting of the limb. However, these devices may be contraindicated in horses that have to stop and turn quickly, because the extension may dig into the footing and stop the distal limb abruptly, causing abnormal torque on the distal limb joints. Removing toe grabs and heel calks and using a flat shoe may reduce shear stress on the distal hock joints.

Intraarticular medication with corticosteroids, such as methylprednisolone acetate or triamcinolone acetonide, with or without hyaluronan, is extremely useful for management of horses with distal hock joint pain. However, horses with extensive radiological abnormalities, especially diffuse radiolucent regions in the subchondral bone, often have a limited response. Horses with scintigraphic abnormalities in the absence of radiological change also respond poorly. Some veterinarians routinely treat both the centrodistal and tarsometatarsal joints of both hocks by using 60 to 80 mg of methylprednisolone acetate in each joint.²⁹ If the competition schedule allows, the horse is turned out for 3 to 4 days, followed by 3 to 4 days of light riding before resumption of normal activity. Phenylbutazone (2.2 mg/kg sid) is also recommended for 7 days to decrease the possibility of postinjection joint flare. Most horses are sound enough to resume work within 7 to 10 days and stay serviceably sound for 3 to 6 months, depending on severity of disease and level of horse use.

Similar results have been achieved using triamcinolone acetonide, 6 mg per joint (SJD). One of us (SJD) does not routinely combine intraarticular therapy with NSAIDs and usually treats only the tarsometatarsal joint. A study by Serena and colleagues demonstrated that therapeutic concentrations of methylprednisolone acetate were achieved in the centrodistal joint within 6 hours of injection of 80 mg into the tarsometatarsal joint in eight of nine horses (in the ninth horse concentrations were similar in both joints, indicating direct communication between the two joints).¹³ However, higher concentrations can be obtained by direct injection. There are no controlled clinical trials assessing the relative efficacy of different corticosteroids or the use of a combination of corticosteroids and hyaluronan, although some clinicians believe that combination therapy lasts longer. Hyaluronan alone is of dubious value. There are also no large-scale, long-term follow-up studies. However, in a retrospective study of 42 horses that were examined at a referral hospital and used predominantly for general purposes or amateur-level competitions and that showed a positive response (>50% improvement in lameness) to intraarticular analgesia of the tarsometatarsal or centrodistal joints, 38% became sound enough to resume full work after intraarticular medication with either

triamcinolone acetonide or methylprednisolone acetate.⁴⁸ In a different study with similar inclusion criteria, 52% of 46 horses were able to return to their former athletic function.⁴⁹ The choice of drug did not influence outcome in either study. Both studies showed no relationship between the severity of radiological abnormality and outcome. However, we believe that this reflects one of the inclusion criteria that horses had to respond to intraarticular analgesia. In our experience horses with extensive subchondral radiolucent areas respond poorly to both intraarticular analgesia and medical treatment.

Corticosteroid injections can be repeated two or three times per year without promoting progressive radiological change. In some horses it is possible to predict when lameness will recur, and repeated treatment before this recurrence can maintain soundness. Although cunean bursitis is rarely recognized as a primary cause of lameness, some horses respond better if intraarticular treatment is combined with treatment of the bursa. In young racehorses with distal hock joint pain, one of us (MWR) uses a combination of intraarticular injection (tarsometatarsal and centrodiscal joints) of a combination of corticosteroids (methylprednisolone acetate [40 to 80 mg/joint] and isoflupredone acetate [2 mg/joint]) and infiltration of this combination of corticosteroids and Sarapin into the cunean bursa and subcutaneously over the proximal aspect of the MtII. It is in this area on the medial aspect of the tarsus and proximal aspect of the metatarsal region that these horses show a positive response to deep palpation (see earlier). A series of intraarticular injections of PSGAG (three injections given every 2 weeks) can be useful in competition horses and racehorses with distal hock joint pain.

Systemic medication with PSGAG (500 mg intramuscularly [IM] once weekly for 6 weeks), hyaluronan (4 mg intravenously [IV] monthly), or oral nutraceuticals may be beneficial as adjunctive therapy. A small-scale study showed reduced frequency of intraarticular medication after the introduction of oral nutraceuticals.⁵⁰ Anecdotally, treatment with PSGAG 3 to 4 days before an event may be useful. In some horses, increasing the dose of PSGAG to 1 g weekly gives better results. Clinical trials with intravenous administration of tiludronate have shown mixed results; overall there was a positive effect on the degree of lameness, but lameness did not resolve in the majority.⁴⁰

In a small-scale study shock wave treatment that was performed with horses under general anesthesia, followed by 5 weeks of rest, resulted in an 80% improvement in lameness in horses 90 days later,³⁹ but long-term results are not available.

A variety of techniques for surgical arthrodesis of the distal hock joints* and subchondral forage⁴¹ exists. Subchondral forage, which aims to reduce intraosseous pressure and therefore pain, can provide rapid pain relief in some horses, enabling return to work. However, this technique has not found widespread favor. Techniques aimed at achieving arthrodesis are more popular, but effective arthrodesis and resolution of lameness often takes up to 12 months using either drill or laser techniques. Careful surgical technique is essential to avoid the development of extensive periarticular new bone, which can itself cause pain. With use of the three-drill tract procedure,^{42,51} a 66%

success rate has been reported.⁵¹ However, the results in upper-level competition horses have been less favorable.³² In Western performance horses a success rate of approximately 70% has been achieved.⁵⁶ Generally both the centrodiscal and tarsometatarsal joints are treated. Cunean tenectomy alone may result in temporary improvement in clinical signs but is unlikely to restore soundness.⁵⁷ Chemical fusion with sodium monoiodoacetate has had excellent results in some horses,^{43,45} with reported success rates of 27 of 29 horses (93%) and 41 of 50 (82%) horses 12 months after treatment. However, even if positive radiographic contrast studies do not show physical communication between the centrodiscal and talocalcaneal-centroquartal joint, it is likely that in some horses sodium monoiodoacetate can spread to these joints and result in progressive OA. Ethyl alcohol can also be used to achieve arthrodesis,⁴⁶ but there are currently no long-term follow-up results, although anecdotally the results are favorable. Arthrodesis of the centrodiscal and tarsometatarsal joints can be followed by either fracture of the central or third tarsal bone or the development of OA in the talocalcaneal-centroquartal joint. Once OA of this joint has developed, there is obligatory involvement of the tarsocrural joint, and chronic, severe lameness ensues. Neurectomy of the deep fibular nerve and a partial neurectomy of the tibial nerves relieves the pain associated with OA of the distal hock joints,⁴⁷ and approximately 60% of treated horses return to full athletic function.

Osteoarthritis of the Talocalcaneal Joint

OA of the talocalcaneal joint is unusual and may occur in isolation^{29,30} or together with OA of the centrodiscal and/or tarsometatarsal joints.³¹ There are frequently no localizing signs, although in a retrospective study there was distention of the tarsocrural joint in six of 18 horses.³¹ Lameness is resolved by perineural analgesia of the fibular and tibial nerves and may be improved by intraarticular analgesia of the tarsocrural joint. Radiological abnormalities are best identified in lateromedial or dorsomedial-plantarolateral oblique images, or in some horses a flexed proximoplantar-distal plantar image, and include subchondral lucency or increased radiopacity and narrowing of the joint space (Figure 44-4). Scintigraphy reveals focal, moderate-to-intense IRU in the subchondral bone of the talocalcaneal joint and can be differentiated from enthesopathy of the attachment of the lateral CL and lesions involving the sustentaculum tali (see later) by acquiring lateral, plantar, and, if necessary, medial and flexed lateral scintigraphic images. Occasionally lesions that are not evident radiologically can be identified using MRI or CT. The prognosis with conservative management is guarded to poor. Surgical arthrodesis has resulted in improvement in, but not resolution of, lameness.³¹

Osteoarthritis of the Tarsocrural Joint

OA of the tarsocrural joint may occur as a primary disease, may develop secondarily to osteochondrosis (see Chapter 56) or OA of the distal hock joints (see page 512), or may be a sequela to trauma. There may be distention of the tarsocrural joint capsule, but this is a variable feature. The joint capsule may feel thickened, more so than observed in horses with idiopathic effusion or a bog spavin as the result of osteochondritis dissecans (OCD). Initially horses

*References 17, 21, 22, 41, 51-56.

Fig. 44-4 • Lateromedial radiographic image of a tarsus of a horse with osteoarthritis of the talocalcaneal joint. Some loss of joint space and irregular subchondral radiolucency (arrows) are present.

respond favorably to intraarticular injections into the tarsocrural joint. There is controversy regarding the association of corticosteroid injections and the subsequent development of OA of this joint. Although in most horses with end-stage OA there is a history of numerous injections including corticosteroids into the tarsocrural joint, this is not always the case. We both believe that there is an association between the presence of OCD and the subsequent development of severe OA in older horses (6- to 8-year-old racehorses and sports horses), whether or not the affected horse had arthroscopic surgery to remove the fragments at a young age.

Lameness varies from mild to severe. Horses with longitudinal wear lines on the trochleas of the talus secondary to OCD of the cranial intermediate ridge of the distal aspect of the tibia often have only mild lameness. However, horses with focal partial- or full-thickness cartilage erosions on weight-bearing parts of the trochleas of the talus may have severe lameness (see Figure 56-11). The response to proximal limb flexion is variable. Lameness usually is partially improved by intraarticular analgesia, but occasionally there are false-negative results. A large volume (up to 50 mL) of local anesthetic solution may be necessary, and often it takes 45 to 60 minutes for lameness to improve in horses with severe OA of the tarsocrural joint. Perineural analgesia of the fibular and tibial nerves results in substantial improvement in lameness. In horses with primary OA of the tarsocrural joint, usually there are no detectable radiological abnormalities, or only subtle evidence of subchondral sclerosis and narrowing of the tarsocrural joint space, and scintigraphic examination is often inconclusive. Diffuse mild IRU may be all that is seen, sometimes localized to the cranial and caudal distal aspect of the tibia. In racehorses, scintigraphic examination often reveals IRU involving the distal aspect of the tibia and proximal aspect of the talus and must be differentiated from subchondral trauma or fracture of the distal tibia and talus.⁵⁸ A flexed lateral

scintigraphic image reveals that IRU involves both sides of the tarsocrural joint, unlike focal uptake, which remains associated with either the talus or the distal tibia. Ultrasonographic examination may reveal synovial proliferation even in the absence of detectable joint effusion. Definitive diagnosis is dependent on arthroscopic examination of the joint. The prognosis for resolution of lameness and return to full athletic function is generally poor to grave. Response to intraarticular medication is often disappointing.

Incomplete Ossification of the Central and Third Tarsal Bones

Incomplete ossification of the central and third tarsal bones is most common in premature or twin foals, but it can occur in full-term singles and is characterized by a sickle-hocked appearance. It may occur unilaterally or bilaterally. Radiologically the bones are smaller and more rounded than usual. Early recognition and treatment are essential to avoid crushing of these bones with resultant progressive OA. Foals with this condition must be rested in a stall or turned out in a small paddock with only their mare. However, many owners or farm managers are loath to give foals rest, and the condition becomes progressive, often leading to collapse and OA and fracture. Cylinder tube casts can be used effectively with good results. In some horses the condition goes unrecognized until a young horse increases work intensity, although the horse may have a preexisting curblike appearance of the hock. Lameness may be sudden in onset despite the existence of advanced radiological changes. Radiological examination reveals a wedge shape of the central and third tarsal bones, which are narrower dorsally (see Figure 128-4). One or more bones may be fractured. There is often advanced OA. Although affected horses may be used for pleasure riding, the prognosis for competition use is guarded.

Distention of the Tarsocrural Joint Capsule

There are many causes of acute or chronic synovitis of the tarsocrural joint (also known as *bog spavin*) including osteochondrosis, OA, trauma, poor conformation, hemarthrosis, infection, and idiopathic causes. There are case reports of eosinophilic synovitis⁵⁹ and ectopic cartilage of unknown origin.⁶⁰ Signalment varies and depends on origin. Clinical signs are excessive tarsocrural joint fluid, which is most easily recognized on the dorsomedial and plantarolateral aspects of the joint. Lameness may or may not be present and is dependent on the cause. Excessive distention of the joint capsule may result in mechanical lameness. Diagnosis is made on the basis of clinical appearance and the response to intraarticular analgesia if the horse is lame. Arthrocentesis may reveal hemorrhage. Oddly, the tarsocrural and antebrachioacral joints are the most common joints in which we have diagnosed intermittent severe lameness as a result of hemarthrosis.²¹ Large vessels that traverse the dorsal aspects of the joint capsules in both joints may be at risk for injury and cause subsequent bleeding into the joint. Radiographic examination should include four standard images, but if no radiological abnormality is detected, flexed lateromedial and flexed dorsoplantar (skyline) images may be helpful. Slightly oblique dorsoplantar images may be necessary to identify OCD of the medial malleolus of the tibia (see Chapter 56). The radiographs should be

inspected carefully for evidence of previous surgery for removal of an osteochondral fragment from the cranial intermediate ridge of the distal aspect of the tibia or other common locations associated with OCD. Occasionally, small fragments remain at previous sites from which OCD lesions were removed, and it is possible that these small fragments or repair tissue at the site may be loose, causing persistent effusion. Lameness in these horses is usually minimal, and the decision to reoperate should be made on a case-by-case basis and reserved for those horses with pain that can be abolished with diagnostic analgesia. Effusion often persists even after removal of OCD fragments from the tarsocrural joint, and persistent effusion is usually not a cause of lameness but may be of concern cosmetically.

Ultrasonography is useful for characterizing the appearance of the fluid within the joint; synovial fluid is anechoic, whereas blood is echogenic. Ultrasonography is also useful for assessment of the thickness of the joint capsule, the presence of synovial hyperplasia, and the thickness of the articular cartilage and may be more accurate than radiography for identification of osteochondral fragments.⁶¹ In the absence of radiological or ultrasonographic abnormalities, a diagnosis of idiopathic synovitis is made.

Treatment of horses with idiopathic synovitis involves fluid drainage and intraarticular injection of either 80 mg of methylprednisolone acetate or 12 mg of triamcinolone acetonide. Combining hyaluronan with the corticosteroids may provide joint protection, but the strong antiinflammatory effect of the corticosteroids seems most beneficial. Pressure bandages should be applied to help maintain joint decompression. Phenylbutazone (2.2 mg/kg) once daily for 7 days and confinement to a small area for 2 weeks is recommended. Approximately 50% of horses have resolution or decrease in effusion, although some horses may require retreatment. Intraarticular injection of atropine (8 mg) is sometimes successful. If joint effusion returns and the horse is not lame, the owner is advised that the horse has a cosmetic blemish that will probably not resolve completely. Horses that are lame and block to the tarsocrural joint but have no radiological lesions are candidates for scintigraphic examination and diagnostic arthroscopy (see discussion of OA of the tarsocrural joint, page 516). Hemiarthrosis is discussed in Chapter 66.

Osteochondrosis of the Tarsocrural Joint

See Chapter 56 for a discussion of osteochondrosis of the tarsocrural joint (page 635).

Subchondral Bone Trauma

With the advent of MRI and CT there is increasing recognition of the role of subchondral bone trauma and pain in causing lameness.⁶² There are anecdotal reports of lesions involving the talus, calcaneus, and central and third tarsal bones, but as yet these lesions have been rather poorly defined, and risk factors and response to treatment have not been documented.

Osseous Cystlike Lesions

Occult osseous cystlike lesions, detected using CT but usually not by radiography, have been recorded in the medial malleolus of the tibia (five horses), intertrochlear groove of the talus (four horses), lateral malleolus (two horses), and cranial intermediate ridge of the distal aspect

of the tibia (one horse).⁶³ We have also seen single or multiple lesions in the distal subchondral bone plate of the tibia and the trochleas of the talus that were detectable scintigraphically and radiologically.⁶⁴ There are usually no localizing clinical signs. Lameness is moderate to severe. In some but not all horses lameness is substantially improved by intraarticular analgesia of the tarsocrural joint. These lesions are associated with focal intense IRU. These lesions are believed to be of infectious or traumatic origin. Conservative management has resulted in persistent lameness in most but not all horses. Surgical curettage may offer a more favorable prognosis, but lesions involving the subchondral bone of the distal aspect of the tibia in the trochlear grooves are not accessible to arthroscopic evaluation and curettage. To access these lesions an extraarticular approach may be necessary. Four of six horses (67%) managed surgically returned to athletic function.⁶³

Fragments in the Talocalcaneal-Centroquartal (Proximal Intertarsal) Joint

The tarsocrural joint communicates directly with the proximal intertarsal joint in immature horses through a slitlike opening and in adult horses through a broad opening in the dorsal reflection of the synovium that is located at the distal dorsal aspect of the talus (see Chapter 56). The proximal intertarsal joint is approached through this synovial fenestration during arthroscopic exploration of the tarsocrural joint. A report describes 17 horses with either a free-floating fragment, which was suspected to have originated and been dislodged from an associated OCD lesion in the tarsocrural joint, or a fragment located at the distal end of the medial trochlear ridge with attachment to the synovial reflection that separates the tarsocrural and proximal intertarsal joints.⁶⁵ However, such fragments can be seen as incidental abnormalities and unassociated with lameness.¹⁸ Fragments associated with the distal aspect of the medial trochlear ridge of the talus can be seen in only a lateromedial radiographic image, whereas loose fragments within the proximal intertarsal joint most often can be seen on numerous radiographic images. Careful examination of the cranial intermediate ridge of the distal aspect of the tibia is necessary, because loose fragments within the proximal intertarsal joint most often dislodge from this location, and a depression will often be seen from which original fragment originated. Fragments associated with the distal aspect of the medial trochlear ridge are often enveloped in the joint capsule separating the tarsocrural and proximal intertarsal joints, medial to the fenestration between the joints. Sharp dissection is necessary to incise capsular attachments, and care must be taken to avoid damage to the articular surface of the central tarsal bone. Fourteen of 17 horses returned to racing or intended performance activity after arthroscopic removal of the fragment.⁶⁵

TARSAL BONE FRACTURES AND LUXATIONS

Fractures of the Distal Tarsal Bones

Fractures of the central and third tarsal bones occur most frequently in STBs, cutting horses, or TB racehorses,⁶⁶⁻⁷⁰ but they occasionally occur in other horses, sometimes secondary to previous fusion of the centrodistal and tarsometatarsal joints. These fractures cause an acute onset of a

moderate-to-severe hindlimb lameness that is usually most noticeable when the affected limb is on the inside of a circle.³² Despite acute onset of lameness, these fractures in young racing TBs may be the result of stress-related bone injury.⁶⁹ The lameness is exacerbated by upper limb flexion. The degree of lameness diminishes after 1 to 2 weeks of rest, but lameness returns if the horse returns to work. Some horses with incomplete fractures of the central tarsal and third tarsal bones can race a number of times before lameness becomes pronounced. On initial diagnosis, some fractures appear chronic in both the TB and STB racehorse. Horses with bilateral third tarsal bone fractures may be examined for poor performance rather than overt unilateral hindlimb lameness. Within STB racehorses in North America, central and third tarsal bone fractures are more common than expected in pacers compared with trotters, even if the normal 3:1 pacer/trotter ratio is considered. Heat, soft tissue swelling, and pain on digital palpation of the distal tarsal bones usually accompany the fracture. Synovial effusion of the tarsocrural joint may occur in horses with central tarsal bone fractures but is not usually seen in horses with third tarsal bone fractures. Intraarticular analgesia is used to diagnose central and third tarsal bone slab fractures, but in some horses, particularly those with incomplete or complete, nondisplaced fractures, fibular (peroneal) and tibial nerve blocks are needed to abolish pain.

Diagnosis is made by radiography or scintigraphy, but a fracture may not be radiologically apparent until up to 10 days after injury, when demineralization of the fracture line occurs. Scintigraphy is useful in horses with mild or bilateral hindlimb lameness. Incomplete or bilateral fractures may be seen. Many fractures can often be identified on a lateromedial radiographic image but most consistently can be seen on a DM-PILO image. If no radiological abnormality is detectable in standard images, additional oblique images, including a plantar 25° lateral-dorsomedial oblique image, should be obtained (or D65° M-PILO image) (Figure 44-5). However, the precise location and orientation of fractures seem to vary between disciplines and

Fig. 44-5 • Plantar 25° lateral-dorsomedial oblique radiographic image of a tarsus. There is a complete slab fracture of the third tarsal bone. This radiographic image is the same projection as a dorsomedial-plantarolateral oblique image showing that the fracture is located on the dorsolateral aspect of the third tarsal bone.

between the central and third tarsal bones. Thus if a fracture is suspected, additional oblique images may be required. CT can be useful to determine the exact location and configuration of a fracture and to pinpoint screw location if surgical repair is elected. In STBs, two types of central tarsal bone fractures are seen. Authentic frontal (dorsal) plane slab fractures extending from the proximal-to-distal articular surfaces of the central tarsal bone are most common and are best seen in either a DM-PILO or lateromedial image (see Figure 44-1). Another type of central tarsal bone fracture courses distodorsally from the proximal aspect of the central tarsal bone in the dorsal plane and breaks out of the dorsal cortex of the bone just proximal to the distal articular surface of the central tarsal bone (Figure 44-6). This second type of fracture can best be seen in a lateromedial radiographic image, and because the fracture line does not appear to extend to the distal articular surface, this fracture may not be an authentic slab fracture. Lameness is pronounced, and horses exhibit identical clinical signs to those with larger fragments. In Western performance horses the fracture line is generally located in a more plantar region of the third and central tarsal bones than is seen in racehorses. Third tarsal bone fractures are most commonly dorsal or dorsolateral. In TB racehorses a wedge-shaped conformation of the dorsolateral aspect of the third tarsal bone may be a risk factor for fracture.⁷¹ Comminuted fractures are more common in the central tarsal bone and may be difficult to identify radiologically.⁶⁷ If comminution occurs, it is usually at the proximal aspect of the fracture, and fragments can be seen and removed using arthroscopic surgical techniques through the tarsocrural joint. Nuclear scintigraphy is invaluable for identifying the likely presence of a fracture if it cannot be determined radiologically.

Fig. 44-6 • Lateromedial digital radiographic image of the right tarsus of a 3-year-old Standardbred filly with pronounced lameness abolished by perineural analgesia of the fibular (peroneal) and tibial nerves. Lameness did not change after intraarticular analgesia of the tarsocrural joint. There is an oblique dorsal plane fracture of the central tarsal bone (arrows) that courses distodorsally from the proximal articular surface of the central tarsal bone and to the dorsal cortex, just proximal to the centrodistal joint. Mild proliferative changes can be seen, indicating that at the time of diagnosis the fracture was chronic.

Horses may be treated conservatively^{69,70,72,73} or surgically.^{67,68,70,71} Seven horses with fractures of the third tarsal bone that were treated conservatively remained lame for 12 months after injury,^{67,68} whereas three horses treated by lag-screw compression returned to racing within 6 months.⁶⁷ Six racehorses with central tarsal bone fractures remained lame, whereas six Quarter Horses treated surgically made a complete recovery.⁶⁸ However, conservative management resulted in return to training within 8 months for 73% of 45 TB racehorses with fractures of the central or third tarsal bone,⁶⁹ and this corresponds with our experience. In a retrospective study 20 of 24 horses with slab fractures of the central tarsal bone were STBs, and of these 82% raced after injury with conservative management.⁷⁰ Of 28 horses with third tarsal bone slab fractures managed conservatively, 25 had unilateral and three had bilateral fractures, and there were 12 TBs, 15 STBs and one Quarter Horse.⁷⁰ After conservative management, 87% of the STBs and 71% of the TBs raced after injury.⁷⁰ During the study period five STBs with slab fractures of the central (one horse) and third (four horses) tarsal bones underwent surgical management with interfragmentary compression, and three raced after surgery.⁷⁰ Ten of 14 STBs (71%) and two of six TBs (33%) returned to racing and started at least five races after injury, and four of five Quarter Horses (80%) returned to previous athletic function with conservative management.⁷² The prognosis in STBs appears satisfactory when conservative management is used, but there appears to be room for improvement in the TB racehorse. We do not know the long-term prognosis of a large group of TB racehorses managed surgically, however. If surgical treatment is performed, case selection is important, because many horses with central tarsal bone fractures have hidden fracture lines that could be inadvertently displaced during screw placement. The large head of a 4.5-mm cortex bone screw may cause soft tissue inflammation and a periosteal reaction. For third and central tarsal bone fractures, 3.5-mm cortex bone screws are preferred. One or two screws should be placed through stab incisions by using radiographic or fluoroscopic guidance, or by using CT. The use of a Herbert cannulated compression screw has been reported.⁶⁸ Horses with fragments that are too small to allow lag-screw fixation, or those with chronic fractures of the third tarsal bone causing OA of the centrodistal or tarsometatarsal joints, can be managed by surgical drilling to facilitate arthrodesis of the joints.

Sagittal Fracture of the Talus

Sagittal fractures of the talus are rare, usually nondisplaced, can be difficult to diagnose, and have been recorded most frequently in STB and TB racehorses,^{74,75} but they can occur in any type of horse. Twelve racehorses had a history of chronic, mild hindlimb lameness that became acutely severe during a race.^{74,75} One of us (SJD) has also seen two endurance horses with acute-onset severe lameness after an endurance race.⁶⁴ Lameness in other types of horses may be associated with trauma. Lameness is moderate to severe and is sometimes associated with distention of the tarsocrural joint capsule. The horse may stand with the limb somewhat protracted and show accentuation of lameness when turning. Intraarticular analgesia may improve lameness but rarely removes it completely, and negative results may also occur. Horses show marked improvement after

fibular (peroneal) and tibial perineural analgesia. Fractures in racehorses usually originate at the proximal aspect of the sagittal groove of the talus and are often incomplete. Nondisplaced fractures can be difficult to identify radiologically; extra images, including a dorsal 10- to 20° lateral-plantaromedial oblique and a flexed dorsoplantar (skyline) image, can be helpful. Fractures caused by trauma are frequently comminuted, and the degree of damage may not be apparent radiologically. Nuclear scintigraphy can be helpful in confirming the presence of a fracture; there is usually intense focal IRU in the proximal aspect of the talus.⁷⁴

Eleven racehorses with incomplete sagittal fractures of the talus were managed conservatively with a minimum of 1 month of stall rest followed by small paddock turnout. Seven returned to racing performance within 7 to 8 months after injury; approximately 50% had the same or improved performance.⁷⁴ Both endurance horses were managed conservatively and returned to full athletic function.⁵⁹ Horses with complete sagittal fractures have been managed by lag-screw compression using two 4.5-mm cortex bone screws.⁷⁰ Prognosis may be favorable in horses with simple acute fractures, but the prognosis for horses with comminuted fractures is poor.

One of us (MWR) has seen two foals that had complete, nondisplaced slab fractures of the talus that healed well with conservative management.⁶⁴ Acute lameness and moderate tarsocrural effusion were found in both foals; the fracture line could best be seen coursing from the proximal-to-distal articular surface of the talus in a dorsal 15° lateral-plantaromedial oblique radiographic image (Figure 44-7).

Fractures of the Fibular Tarsal Bone

Fractures of the fibular tarsal bone (or calcaneus) are uncommon and usually the result of trauma. Physeal fractures in foals and fractures through the body of the bone are easily diagnosed because of the obvious loss of gastrocnemius muscle function, which results in a dropped-hock appearance. Chip fractures involving the plantar aspect of the calcaneus can be difficult to diagnose unless soft tissue swelling is present or a draining tract secondary to sequestra formation exists. Surgical removal of small fragments may be necessary, depending on size and location of the fragment (intraarticular or extraarticular). Diagnosis is confirmed radiologically. Flexed lateromedial and skyline images of the calcaneus are recommended in addition to standard views (Figure 44-8). Complete body and physeal fractures can be difficult to reduce and stabilize, but horses can be managed successfully with bone plates, screws, and wires by using the tension-band principle. It is not possible to place a bone plate directly plantar because of the presence of the superficial digital flexor tendon, but the plantarolateral or lateral surface of the calcaneus has been used successfully. One of us (MWR) has used a combination of interfragmentary compression and figure-eight tension band wiring to successfully repair fractures of the calcaneus in two miniature horses.⁶⁴ Conservative therapy using casting methods alone has been unrewarding and is not recommended. Horses with open, comminuted fractures have a grave prognosis, and humane destruction should be advised. Prognosis for future performance activity in horses with physeal or full-body fractures is considered poor.

Fig. 44-7 • Initial (**A**) and 6-week follow-up (**B**) digital dorsal 15° lateral-plantaromedial oblique radiographic images of a suckling Standardbred foal with acute hindlimb lameness and moderate tarsocrural joint effusion. **A**, A non-displaced sagittal fracture of the talus can be seen (*arrows*) coursing from the proximal-to-distal articular surfaces. **B**, Six weeks later the fracture line appears blurred and cannot be seen at the proximal aspect of the talus but can still be seen at the distal aspect (*arrows*). This foal made a complete recovery using conservative management consisting of 10 weeks of box stall rest. Fig. 44-8 • Flexed lateromedial radiographic image of a tarsus. There is a complete, comminuted articular fracture through the calcaneus.

Fracture of the Lateral Malleolus of the Tibia

The lateral malleolus is considered to be the distal end of the fibula and develops as a separate center of ossification that fuses to the distal tibial epiphysis by 1 year of age. The long lateral and deeper short CLs originate on the lateral malleolus of the tibia, just plantar to the groove for the tendon of the lateral digital extensor muscle. Only a small portion of the lateral malleolus is intraarticular; therefore most fracture fragments are located within the joint capsule

and CLs. The lateral malleolus is mostly covered by soft tissue attachments; therefore careful dissection and the use of a motorized synovial resector are necessary for successful removal of fracture fragments using arthroscopic techniques.

Lateral malleolar fractures are usually traumatic in origin. Small, well-rounded fragments, probably a manifestation of osteochondrosis, occur occasionally and should be differentiated because horses are often asymptomatic. Clinical and radiological signs and results of surgical removal of the fragments have been reported in 16 horses.⁷⁶ All were TBs with injuries incurred either during a fall in a race over fences or from being kicked. All horses had a moderate degree of lameness and tarsocrural effusion. Approximately 50% of the horses had periarticular swelling, thickening of the CL, and pain on digital palpation of the lateral malleolus. All fractures were visible on a dorso-plantar radiographic image (Figure 44-9). Fourteen fractures were unilateral and two bilateral, with nine simple and nine comminuted. Thirteen of 16 fragments were displaced distally and rotated 90 degrees.

Ultrasonographic evaluation is useful to determine the location of the fracture in a dorsoplantar plane and to identify a concurrent collateral desmitis.²² Horses with small or minimally displaced fractures have been successfully managed conservatively. Surgical removal may result in a quicker recovery. The tarsocrural joint should be inspected arthroscopically to remove any debris, and surgical removal of most fragments is possible; use of a motorized synovial resector facilitates debridement of the joint capsule and CL attachments to the fracture fragment. In some horses the fragment can be easily removed via an incision through the lateral CL of the tarsocrural joint, depending on fragment orientation. Thirteen of 16 horses treated by fragment removal returned to full athletic function.⁷⁶ If the fracture fragment is of adequate size or if there

Fig. 44-9 • Dorsoplantar radiographic image of a tarsus. There is a fracture of the lateral malleolus (arrow).

is instability of the tarsocrural joint, lag-screw fixation and tension band wiring should be considered. One of us (MWR) examined a horse with lateral and medial malleolar fractures; repaired the larger, comminuted, displaced lateral malleolar fracture using a single 4.5-mm cortex bone screw placed in lag fashion augmented by a figure-eight tension band wire; and repaired the nondisplaced medial fracture using interfragmentary compression.⁶⁴ The repair was performed using conventional surgical techniques, and small fragments originating from the lateral malleolus were removed. With conservative or surgical management the prognosis is good.

Fractures of the Medial Malleolus of the Tibia

Fractures of the medial malleolus of the distal tibia are rare. Similar to fractures of the lateral malleolus (see earlier), occasionally, small rounded fragments are displaced distal to the medial malleolus, intercalated in the medial CL. These fragments may be a manifestation of osteochondrosis and are distinct from the more common OCD fragments originating from the cranial, articular component of the medial malleolus (usually axially), in the tarsocrural joint. Alternatively, these rounded fragments may be the result of an old fracture. Authentic fracture of the medial malleolus occurs rarely alone, or in combination with lateral malleolar fractures (see earlier).^{64,77,78}

Tarsal Joint Luxation

Complete luxation or subluxation of the tarsocrural, talocalcaneal-centroquartal (proximal intertarsal), and tarsometatarsal joints may occur, with or without concurrent tarsal bone fractures.^{79,80} Tarsal luxations are the result of severe trauma from kicks from other horses or limb entrapment in fixed objects, such as a fence or cattle guards. Proximal intertarsal and tarsometatarsal luxations are most common. Luxation causes severe, non-weight-bearing lameness, and there may be abnormal deviation of the limb

Fig. 44-10 • Flexed lateromedial image of a hock. There is widening of the plantar aspect of the talocalcaneal-centroquartal joint (arrows), which is indicative of luxation.

Fig. 44-11 • Stressed dorsoplantar image of a hock. There is luxation of the tarsometatarsal joint, which is associated with fracture of the third and fourth tarsal bones.

at the tarsus. Crepitus may be present with a fracture, and palpation reveals tarsal joint instability. Diagnosis is confirmed by radiological examination. Dorsoplantar radiographic images obtained with medial or lateral limb traction are recommended to determine the extent of CL damage (Figures 44-10, 44-11, and 44-12). Treatment consists of

Fig. 44-12 • Stressed dorsoplantar image of a hock. There is luxation of the tarsocrural joint.

reduction of the luxation with the horse under general anesthesia and stabilization with the application of a full hindlimb cast extending from the foot to a point level with the tibial tuberosity. Alternatively, external coaptation consisting of a Robert Jones bandage with splints (custom-made) or external cast material (cast, bandage) can be applied to a standing, sedated horse. Although reduction will be less than ideal and invariably an angular deformity will persist, a successful outcome can be achieved.⁶⁴ Internal fixation is rarely indicated but may be necessary with concurrent tarsal bone fracture. Double plating techniques using conventional or locking compression plates applied proximal to the fracture or luxation using the plantarolateral aspect of the calcaneus and the medial aspect of the hock and ending distally in the metatarsal bones, in combination with external coaptation, could be used. Tarsocrural or tarsal luxation with functionally intact CLs can be difficult to reduce, but manipulation of the tarsus with the limb in a flexed position may facilitate reduction. The limb should be maintained in a cast or other external coaptation constructed to be as rigid as possible for 4 to 6 weeks if the CLs are intact and 6 to 8 weeks if the CLs are ruptured.^{79,80} After the cast has been removed, the hindlimb is placed in a heavy cotton bandage with rigid splints for an additional 4 to 6 weeks before turnout in a small area is allowed. Of the seven reported horses with tarsal joint luxation (three proximal intertarsal, three tarsometatarsal, and one tarsocrural), all were treated with closed reduction and external coaptation, and all returned to either light riding, pasture soundness, or breeding activity. The presence of tarsal bone fractures did not affect outcome. All horses had a reduction in range of motion of the tarsus and OA that prevented the return to athletic soundness. Prognosis for horses with

proximal intertarsal and tarsometatarsal joint luxations is reasonably good for pasture soundness.⁷⁹ A guarded prognosis is warranted for horses with tarsocrural joint luxation because of the difficulty in reducing the luxation.

SOFT TISSUE INJURY OF THE TARSUS

Various soft tissue injuries of the tarsus are discussed elsewhere: calcaneal bursitis (see Chapter 79), cunean tendon bursitis-tarsitis (see Chapter 108), curb (see Chapter 78), subcutaneous calcaneal bursitis (capped hock; see Chapter 79), distention of the tarsal sheath (thoroughpin; see Chapter 76), and dislocation/luxation of the superficial flexor tendon from the tuber calcanei (see Chapter 80). Distention of the long digital extensor tendon sheath is discussed previously (see page 509).

Collateral Ligament Damage

Complete extension of the tarsocrural joint is prevented by tension in the CLs. CL injury is usually the result of trauma or a fall; however, it is not a common injury. CL injury was identified in only 23% of 133 horses that underwent ultrasonographic evaluation of the tarsus because of suspected soft tissue injury.²² Lameness varies from mild to severe, depending on the degree of damage. There is often distention of the tarsocrural joint capsule and periarticular soft tissue swelling. Flexion is usually resented. Analgesic techniques are usually not required, but lameness may be improved in some horses by intraarticular analgesia of the tarsocrural joint. In an acute injury there often are no radiological abnormalities unless there is an avulsion fracture⁸¹; however, 4 to 6 weeks after injury, enthesophytes develop at the origin or insertions of the injured CLs. Nuclear scintigraphy is helpful in horses with mild injuries because it demonstrates intense, focal IRU at the ligament attachment sites.⁸² Ultrasonographic evaluation is used to identify the injured structure(s) and assess the severity of the injury (see Chapter 17).²² In a series of 23 horses, 18 sustained medial CL injury, including three with both medial and lateral CL injury, and five horses had lateral CL injury alone, with injury to the superficial components being most common either alone or together with injury to the deep component. Initial treatment involves stall rest, cold water therapy, topical dimethyl sulfoxide with or without corticosteroids, and NSAIDs. Long periods of rest (e.g., 6 months) followed by a controlled exercise program have been recommended.⁸¹ Prognosis depends on the severity of injury, but horses with very extensive periosteal new bone have been able to return to full athletic function, although some residual enlargement of the hock has persisted.^{21,64}

Old avulsion fractures at the insertion of the lateral and less commonly the medial short CL are sometimes detected in horses with pain causing lameness localized to the hock with no other explanation for the cause of lameness. There is no associated IRU, and the clinical significance of such fractures is difficult to determine accurately. It is conceivable that low grade motion may cause pain.

Enthesopathy of the Lateral Collateral Ligaments of the Tarsocrural Joint

Enthesopathy of the long, and less commonly, the short lateral CLs is a rare condition that is recognized most often

in STB racehorses, especially pacers, but does rarely occur in TBs. It results in lameness that is improved by analgesia of the tarsocrural joint. There may be distention of the tarsocrural joint capsule, and subtle, localized soft tissue swelling may be present. Diagnosis usually depends on scintigraphic findings⁸³ with focal, intense IRU on the lateral aspect of the calcaneus. Entheseous new bone is usually detectable radiologically. Local injections with methylprednisolone acetate and Sarapin, an extract of the pitcher plant, may result in improvement, but rest is the treatment of choice.

Rupture of the Fibularis Tertius

See Chapter 80 for a discussion of rupture of the fibularis (peroneus) tertius.

Stringhalt

See Chapter 48 for a discussion of stringhalt.

MISCELLANEOUS TARSAL INJURIES

Osseous Cystlike Lesions in the Tuber Calcanei

Osseous cystlike lesions in the tuber calcanei have been identified as a cause of moderate to severe lameness either with no localizing clinical signs (Figure 44-13)⁶⁴ or in association with distention of the calcaneal bursa.⁸³ It has been suggested that such lesions may be a reaction at the enthesis of the gastrocnemius tendon, but no associated lesions of the gastrocnemius tendon have been seen.⁸⁴ In two horses lameness developed after known trauma (a kick and a fall),⁸⁴ but in other horses there was no known potential cause. In the latter horses lameness was abolished by fibular and tibial nerve blocks. Lateromedial, dorsolateral-plantaromedial oblique and skyline images of the calcaneus are required for accurate localization of the lesion. Treatment of two horses with associated distention of the calcaneal bursa by either conservative management or surgical debridement resulted in persistent lameness.⁸⁴ The horses

with no associated soft tissue swelling did not respond to rest, but intralesional injection of corticosteroids has resulted in resolution of lameness in two horses.⁶⁴ Calcaneal bursitis is rarely caused by primary injury of the gastrocnemius tendon at the attachment to the calcaneus or a combined injury of the gastrocnemius and superficial digital flexor tendons (see Chapters 79 and 80).

Infectious (Septic) Osteitis of the Calcaneus

Osteitis of the tarsal bones is uncommon. However, the enlarged end of the tuber calcanei has minimal soft tissue protection and is at risk for traumatic injury and subsequent infection. Management of these injuries can be complicated if the tarsocrural joint, calcaneal bursa, or tarsal sheath is involved. Most horses sustain a traumatic injury from kicking a fixed object or being kicked by another horse.^{85,86} Osteitis usually causes moderate-to-severe lameness, cellulitis, and tarsal tenosynovitis. The severity of lameness often decreases once drainage has been established. Twenty-two of 28 horses had a wound or draining tract over the plantar aspect of the calcaneus.⁸⁵ Lateromedial, flexed lateromedial, and plantaroproximal-plantarodistal (skyline) radiographic images are the most helpful (Figure 44-14). Radiological signs of calcaneal osteitis or sequestra formation may take several days or weeks to appear, and thus sequential radiological evaluation is recommended. Rarely is the medullary cavity of the calcaneus involved; hence the term *osteitis* rather than *osteomyelitis* is preferred. Ultrasonography is useful to assess calcanean bursa or tarsal sheath involvement. If tarsal sheath involvement is suspected, cytological evaluation of the tendon sheath fluid with aerobic and anaerobic microbial culture and susceptibility testing is recommended (see Chapter 76). Treatment is based on resolving the infection and debriding any bony lesions. Debridement can often be done using bursoscopic techniques, but if wound revision is needed a conventional surgical approach to the infected bone can be used. One of us (MWR) has had success in

Fig. 44-13 • Flexed plantaroproximal-plantarodistal radiographic view of the calcaneus. There is a well-defined focal osteolytic lesion in the plantarolateral aspect of the tuber calcanei (arrow). Compare with Figure 44-14. There were no localizing clinical signs.

Fig. 44-14 • Flexed plantaroproximal-plantarodistal radiographic view of the calcaneus. There is an osteolytic lesion in the tuber calcanei (arrows), the result of infection. There is also new bone on the lateral aspect (to the left) of the calcaneus.

managing horses with infectious calcaneal bursitis and calcaneal osteitis, using liberal debridement and primary wound revision and closure, closed suction drainage, and external coaptation using a full-limb or sleeve cast or bandage to immobilize the tarsus after surgery. External coaptation appears important in overall management because limiting motion improves the horse's comfort and allows early healing of revised wounds in this region. Although debridement of all infected bone and soft tissue is an important principle in management of horses with infectious osteitis of the calcaneus, aggressive debridement of the calcaneus to remove large amounts of bone should be avoided. Broad-spectrum antimicrobial drugs such as penicillin (22,000 IU/kg q12h IM) and gentamicin sulfate (6.6 mg/kg q24h IV) are recommended until culture results are known. Pure bacterial cultures were isolated in 14 of 28 horses in one report,⁸⁵ but mixed bacterial isolates do occur. The most common pure bacteria colonies isolated were *Escherichia coli*, *Streptococcus zooepidemicus*, *Staphylococcus aureus*, and *Enterobacter cloacae*. All isolates were susceptible to penicillin, gentamicin, or trimethoprim sulfamethoxazole. With acute infection, antimicrobial medication alone may be satisfactory, but surgical intervention to remove infected soft tissue and damaged bone or sequestra is usually required. Resection of the infected soft tissues and curettage of the bony lesion can resolve calcaneal lesions that do not involve the tarsal sheath. Infections involving the tarsal sheath require flushing the sheath and establishing drainage (see Chapters 24 and 76). Duration of antimicrobial therapy depends on clinical response, but therapy should continue for at least 7 days after resolution of the lameness and wound drainage. Phenylbutazone (2.2 mg/kg orally [PO]) should be used as needed for pain relief.

The prognosis for horses with calcaneal osteitis depends on the structures involved, duration of infection before treatment, type and susceptibility of isolated bacteria, and the ability to get the original wound to heal. Long-term management (several weeks to months) is often needed, and an important but often limiting factor is the owner's financial commitment. Chronic persistent drainage, persistent severe lameness, or contralateral laminitis can negatively influence prognosis, and aggressive, expensive therapy is often needed. Quick and aggressive medical and surgical treatment improves the chances of horses returning to athletic function. In one study, nine of 18 horses were used as broodmares and nine returned to athletic function.^{85,86}

Osteitis of the Sustentaculum Tali

The sustentaculum tali is on the plantaromedial aspect of the calcaneus. Injuries involving the medial aspect of the hock often involve the sustentaculum tali and adjacent tarsal sheath. Injury usually occurs from direct trauma, most commonly from a kick wound. Lameness is often severe. Diagnosis can be difficult because of the severe soft tissue swelling that accompanies this injury, especially when acute. Although unusual, there can be communication of the site of infection or fragmentation of the sustentaculum tali with the tarsocrural joint. Radiographic examination should include dorsomedial-plantarolateral oblique, dorsoplantar, and plantaroproximal-plantarodistal images. Ultrasonography is useful to assess the deep digital

flexor tendon (DDFT) and tarsal sheath. Infection of the tarsal sheath as a result of sustentaculum tali fragmentation (see Figure 76-3) or lysis requires surgical curettage of the sustentaculum tali and lavage and flushing of the tarsal sheath. Horses with bony irregularities in the tarsal groove of the sustentaculum tali can be severely lame, even without infection, because of motion of the DDFT against the roughened bone, which results in severe tendonitis. The tarsal retinaculum can become constrictive if the tendon is inflamed and swollen, which causes further tendon damage and pain. Surgery with the horse under general anesthesia is recommended to transect the tarsal retinaculum, explore and curette necrotic bone involving the sustentaculum tali, and drain and flush the tarsal sheath.⁸⁷ The tarsal groove should be smoothed with a curette to avoid abrasion to the DDFT after surgery. Endoscopic examination of the tarsal sheath may be difficult in horses with severe swelling from concomitant infection. In horses with mild swelling, with drainage localized to the region of the sustentaculum tali, and without substantial tarsal tenosynovitis, a small incision should be made directly over the fragments. The fragments should be removed and the site curetted; the incision is closed primarily. In these horses, prognosis for future soundness is favorable. Horses should be treated with systemic antibiotics based on culture and susceptibility results. Antimicrobial therapy is continued for at least 7 days after resolution of clinical signs and may require 4 to 6 weeks of treatment. After surgery, horses should be confined to a stall or small run for 8 weeks with daily handwalking, followed by 6 more weeks of pasture turnout before returning to normal activity. Prognosis is good for returning to athletic activity. Seven of nine horses returned to previous use (three barrel racing, one cutting, and three pleasure riding) after surgery.⁸⁷

Lesions of the Sustentaculum Tali

Lesions of the sustentaculum tali of the fibular tarsal bone may occur as a result of known direct trauma, such as a kick injury to the medial aspect of the hock,⁸⁸ or in association with chronic injuries of the DDFT. Eight of eight horses with proliferative new bone on the plantar and/or medial aspect of the sustentaculum tali had marked distention of the tarsal sheath and lameness. Four had a history of a kick injury. Conservative or surgical management resulted in persistent lameness. Postmortem examination revealed marked fibrillation of the DDFT and adhesions to the tarsal sheath and/or the sustentaculum tali.

Chronic lesions of the DDFT may be associated with the development of dystrophic mineralization within the tarsal sheath and osseous irregularity of the sustentaculum tali. Distention of the tarsal sheath and lameness are present. The prognosis is poor.

Congenital Deformations of the Tarsus

Congenital dysplasia of the sustentaculum tali is rare and has been documented in TBs⁸⁹ and Saddlebreds characterized clinically by a tarsal valgus conformation and a broader plantar profile than usual. The DDFT is positioned more dorsally and medially than usual because of flattening of the proximal aspect of the sustentaculum tali.

A complete fibula may be present in Shetland ponies.^{90,91} This results in an abnormal swelling on the distal lateral

aspect of the tibia and outward splaying of the limbs distal to the hocks.

Infectious Arthritis

See Chapter 65 for a discussion of infectious arthritis.

Periarticular Cellulitis (see also Chapter 107)

Peritarsal infection results in acute-onset, very severe non-weight-bearing lameness associated with localized swelling that is usually but not invariably on the dorsal aspects of the hock. The swelling is hot and exquisitely painful to palpation. These signs are associated with an elevated rectal temperature, neutrophilia, and hyperfibrinogenemia. In

some horses, skin abrasions can be identified somewhere in the more distal part of the limb.

Prompt, aggressive treatment with oxytetracycline (5 mg/kg IV sid) or other antimicrobial agents and phenylbutazone (4.4 mg/kg) for at least 5 days, combined with forced walking exercise for as much as possible daily, usually results in rapid resolution of lameness. Horses can often start trotting within 3 days of the onset of clinical signs and should be trotted for 10- to 15-minute periods repeatedly through the day. The prognosis is usually favorable; 1 of 10 horses developed osteomyelitis of the third tarsal and fourth tarsal bones, although this horse ultimately made a complete recovery.⁹²

Chapter 45

The Crus

Mike W. Ross

ANATOMY

The crus is located between the stifle and hock joints. Anatomy of the hock and stifle are discussed in Chapters 44 and 46. The medial aspect of the tibia lacks muscle covering and is easily palpated, but muscles and tendons cover the cranial, lateral, and caudal aspects. The tibia has proximal and distal physes and a separate center of ossification for the tibial tuberosity.

The fibula is lateral, does not share axial load, and fuses with the tibia to form the lateral malleolus. The proximal aspect of the fibula may develop from two or more separate centers of ossification, and fibrous union may persist throughout life. The result of this union is transverse radiolucent lines that are evident radiologically and should not be mistaken for fractures (see discussion of rare fibular fractures later).^{1,2}

Muscles and tendons of the crus are important in locomotion and support of the hindlimb. The long digital extensor muscle originates from a common tendon with the fibularis tertius from the extensor fossa of the femur and is located cranially and laterally in the crus. The fibularis tertius courses distally to divide into dorsal and dorsolateral tendons of attachment. Avulsion injury of the tendon of origin of the fibularis tertius and long digital extensor causes a classic disruption of the hindlimb reciprocal apparatus. The tibialis cranialis muscle is deep to the long digital extensor muscle and distally splits into two parts, the medial of which is called the *cunean tendon* (jack tendon) and may play a minor role in distal hock joint pain. The lateral digital extensor muscle originates proximally, and its tendon courses laterally over the tarsus and joins the long digital extensor muscle in the proximal metatarsal region. Myotectomy of the lateral digital extensor tendon and muscle is often performed for management of stringhalt.

The paired gastrocnemius muscles originate from the distal, caudal aspect of the femur and share a single, strong tendon that courses distally and inserts on the calcaneus. The superficial digital flexor and deep digital flexor muscles and tendons arise caudally. The superficial digital flexor tendon (SDFT) begins medial to the gastrocnemius tendon and courses from medial to caudal to attach to the calcaneus before continuing distally. The deep digital flexor tendon (DDFT) is deep to both the SDFT and the gastrocnemius tendons and courses distally over the plantaromedial aspect of the calcaneus, the sustentaculum tali. The combined SDFT and gastrocnemius tendons form the common calcaneal tendon, the major extensor of the hock, and injuries can cause partial or complete loss of hock support. The tarsal sheath begins in the distal, caudal aspect of the crus and surrounds the DDFT.

The fibular (peroneal) nerve originates from the sciatic nerve and branches in the proximal aspect of the crus to become the superficial and deep fibular nerves that run between the long digital extensor and lateral digital extensor muscles and tendons. The tibial nerve is palpable in the distal, caudal aspect of the crus, cranial to the common calcaneal tendon.

CLINICAL CHARACTERISTICS AND DIAGNOSIS OF LAMENESS OF THE CRUS

Degree of lameness can vary from a subtle, high-speed lameness seen in horses with early stress-related bone injury to an acute, non-weight-bearing lameness, swelling, and deformity seen in horses with complete tibial fractures. Horses with tearing of the gastrocnemius tendon, musculotendonous junction, origin, and insertion have varying degrees of hyperflexion of the tarsocrural joint and partial loss of the reciprocal apparatus. Because the hock drops during weight bearing, the degree of pelvic hike is less than expected and the degree of lameness may be underestimated. Foals with fibularis tertius and long digital extensor avulsion injury lose integrity of the reciprocal apparatus and have swelling on the lateral, proximal aspect of the crus. Rarely, foals can injure the fibularis tertius distally near the tarsus. Fibularis tertius injury in adult horses may cause swelling of the distal, cranial aspect of the crus near the tarsocrural joint, but lesions in the midcrus are not associated with swelling. In callosities circumscribed, round-to-oblong, nonpainful

mineralized masses are attached to the distal aspect of the lateral patellar ligament and lateral femorotibial joint capsule or collateral ligament.

No gait characteristics are pathognomonic for pain associated with the crus. Lameness of the crus is similar to that seen in horses with pain originating anywhere from the tarsus to the hind foot. Horses with tibial stress fractures have a shortened cranial phase of the stride and, most often, a stabbing type of hindlimb gait when viewed from behind. Injuries of the crus should be suspected when lameness is pronounced, but sites in the rest of the limb are eliminated by using diagnostic analgesia. In Thoroughbreds (TBs), in which the risk of tibial stress fractures is high, a tentative diagnosis of stress fracture is made when lameness is pronounced and recurrent after work.

Palpation of the crus should be done with the limb in both the standing and flexed positions, but this often yields no information. The medial side of the tibia is most easily felt, and occasionally in horses with tibial stress fractures, mild swelling is present and pain is elicited by deep compression (see Figure 6-27). Unfortunately, most tibial stress fractures involve the caudolateral cortex, and it is difficult to compress this area during palpation. Digital tibial percussion sometimes elicits a painful response in horses with tibial stress fractures, but there are many false-positive and false-negative responses. Forced tibial torsion with the limb in a flexed position may elicit pain in horses with tibial stress fractures (see Chapter 107), but I have found the results of this test to be inconsistent.

Diagnostic Analgesia

There is no practical method to use diagnostic analgesia in the entire crus. The distal portion is blocked when fibular and tibial nerve blocks are performed, and pain from injuries involving the distal aspect of the tibia and caudal soft tissues may be abolished, but this block is unreliable for abolition of crus-related pain. Lameness of the crus becomes more likely in horses in which perineural and intraarticular techniques for the rest of the limb have been exhausted. In at least three TB racehorses, pain associated with tibial stress fractures has been abolished or diminished by intraarticular analgesia of the femorotibial joint. An explanation is not readily apparent.

Imaging Considerations

Large cassettes or imaging plates (35 × 43 cm) should be used to obtain radiographs of the entire length of the tibia. There are normal areas of modeling involving the cranial proximal cortex of the tibia that appear as layers or a mound of bone, but stress fractures do not occur here. Occasionally, an obvious bony proliferation is seen involving the caudal or caudolateral tibial cortex, under the fibula in normal horses. Periosteal and endosteal proliferation of the caudal and lateral (medial is unusual) cortex and oblique linear radiolucency are changes that may be seen in horses with tibial stress fractures. Enostosis-like lesions appear as single or numerous medullary radiopacities. In some horses the fibula has one or more transverse radiolucent lines through the proximal third of the bone that should not be mistaken for fractures. Stress-related bone injury of the tibia is most easily imaged and diagnosed using scintigraphic examination. Without scintigraphy the diagnosis can be easily missed radiologically. Enostosis-like lesions may be

associated with single to numerous areas of increased radio-pharmaceutical uptake (IRU) in the medullary cavity and should be differentiated from the cortical uptake associated with tibial stress fractures. Numerous scintigraphic images are used to differentiate enostosis-like lesions, tibial stress fractures, and rare authentic lesions of the fibulae.

Ultrasonographic examination is useful in evaluating the gastrocnemius muscle and tendon. Patellar desmitis at the attachments can be diagnosed by using ultrasonographic and scintigraphic examinations. Ultrasonographic examination is useful in horses with fibularis tertius injury or thoroughpin or “false” thoroughpin and to evaluate the tarsal sheath.

SPECIFIC CONDITIONS OF THE CRUS

Tibial Stress Fractures

Tibial stress fractures are the most common lameness condition of the crus and occur most commonly in TB racehorses. In my experience, tibial stress fractures are rare in other sports horses, including the Standardbred (STB) racehorse. In an 8-year period, of 1020 STBs in which scintigraphic examination was performed, only three horses (two of which were trotters) had tibial stress fractures.³ Thirteen STB racehorses, 11 pacers, and two trotters with tibial stress fractures were reported in one study,⁴ but based on my experience this is a highly unusual clustering of horses. In that study pacers were overrepresented, and factors such as breeding, track size, training methods, and referral bias may have played a role. In my experience and practice area tibial stress fractures occur more commonly in trotters than in pacers. The caudal tibial cortex appears prone to stress-related bone injury because it is under compressive forces when loaded. The highest compressive forces were recorded in the middiaphysis at the walk, but loading at the gallop, pace, and trot was not determined.⁴⁻⁶

Tibial stress fractures usually occur in 2- and 3-year-old TB racehorses. In one study, tibial stress fractures occurred most commonly in 2-year-olds or unraced horses.⁷ In my experience tibial stress fractures occur later in training than stress fractures of the humerus, can occur when horses are racing, and also occur in older horses. Lameness in horses with humeral stress fractures often occurs within 4-8 weeks of returning to training in the early 3- or 4-year-old racing year. In horses with tibial stress fractures usually lameness is unilateral. Stress-related bone injury is more advanced in the lame limb, but scintigraphic evidence of stress-related bone injury can be bilateral. Typically TB racehorses with tibial stress fractures usually become acutely lame after training or racing, only to become reasonably sound within 3 to 5 days. Lameness recurs after another work session or race, but overt clinical signs other than lameness are subtle or lacking. Horses with pelvic stress fractures and those with stress-related bone injury of the distal aspect of the third metatarsal bone manifest similar clinical signs. Lameness may be severe initially, but within a few days horses can be trotted and show grade 2 to 4 lameness (of 5). Lameness may be worse in horses with caudal or caudomedial stress fractures than in those with caudolateral stress fractures. Horses with spiral tibial fractures involving the medial and lateral cortices and often the cranial cortex of the distal aspect of the tibia can be nearly non-weight bearing (see Figure 19-10).

Tibial stress fractures are seen as focal areas of IRU in the caudal or caudal lateral tibial cortex in the middiaphysis and are usually singular but can be multiple and bilateral (see Chapter 19). Tibial stress fractures must be differentiated from enostosis-like lesions, which can cause similar clinical signs but scintigraphically are located in the medullary cavity (see Figure 19-9). Caudomedial tibial stress fractures occur but are unusual. In horses in North America, tibial stress fractures are usually located from middiaphysis to the distal aspect of the tibia, but occasionally a fracture is seen in the proximal, caudal metaphyseal region. In TBs racing in Europe the proximal caudal site is affected more commonly than is seen in TBs from North America.⁸ Of 42 TB racehorses with tibial stress fractures examined in England, 52% had middiaphyseal fractures, 29% had distal tibial fractures, and 19% had proximal caudal fractures.⁹ In Australia fracture distribution mimics that seen in North America.⁷ Occasionally a spiral fracture of the distal tibial cortex is seen scintigraphically, but fractures are usually initially not detectable radiologically (see Figure 19-10). Horses with this configuration of fracture are at risk for catastrophic failure of the tibia, even while being stall rested. In general, intensity of IRU is inversely proportional to the amount of radiological change. In a U.K. study in Newmarket, no correlation was found between scintigraphic and radiological grades in TB racehorses.⁹ Curiously, there was no relationship between scintigraphic grade and degree of lameness, a finding that differs from my clinical experience.⁹ This may reflect the rapidity with which horses undergo scintigraphic examination in a first-opinion racehorse practice, compared with the delay before horses are referred to my second-opinion practice. In horses with stress-related bone injury a continuum of bone changes occurs; these bone changes precede and eventually lead to fracture. If radiographs show proliferative changes and an oblique fracture line, IRU is usually mild to moderate. In horses that develop sudden, severe lameness, focal or spiral intense IRU is seen, but radiological changes are equivocal or mild. Authentic tibial stress fractures do not occur in the cranial cortex (except distally in horses with spiral fractures), but IRU from a previous fibular nerve block can produce an artifact resembling fracture (see Figure 19-15).

Most horses are given 4 weeks of stall rest, followed by 4 weeks of stall rest with handwalking, then 8 weeks of turnout in a small paddock before returning to race training. In North America it is difficult to enforce a 16-week rest period, but earlier return to race training predisposes to recurrence of stress-related bone injury and fracture. Trainers are often content with a 45- to 60-day period of rest but balk at giving longer rest periods; however, fractures heal neither clinically nor scintigraphically in 60 days. Because stress fractures occur as a result of accumulated bone stress from race training, early return to training on the very surface on which the horse was training when the fracture occurred and in the same training regimen predisposes to reinjury. Fracture of the contralateral limb the next racing year is possible, but recurrence of ipsilateral fracture is unusual, unlike recurrence seen early in training in horses with humeral stress fractures. Horses with severe lameness may have difficulty rising in the stall and should be bedded on good footing or kept in the standing position for several weeks by the use of crossties or other suitable restraints. Clients should be warned that even while horses are resting, spiral tibial fractures can become comminuted.

Tibial Diaphyseal Fractures in Adult Horses

Tibial fractures in adult horses occur from trauma from falling, from spills (falls) sustained while performing, from being kicked, or during attempts to rise after general anesthesia. Horses with tibial stress fractures, usually those with severe initial lameness or spiral fracture, can develop comminuted fractures if turnout exercise is given too soon or if a horse struggles to rise in a stall. One of the only reported successful repairs of an adult horse with a displaced tibial fracture was performed after the horse had been anesthetized for radiographs of the pelvis and coxo-femoral joint only to develop a displaced, closed tibial fracture as a result of displacement from a tibial stress fracture. The injury was repaired using two dynamic compression plates and bone screws.¹⁰ In general, however, prognosis is grave for adult horses with displaced, comminuted tibial fractures, because comminution is severe, additional fracture lines often propagate proximal and distal from the fracture site, fractures are often open, and implant failures are common (Figure 45-1). Prognosis for horses with comminuted fractures involving the distal aspect of the tibia and tarsocrural joint is hopeless. A horse with a closed, simple, or mildly comminuted mid-shaft oblique or transverse fracture may be a candidate for an attempt at internal fixation. With newly developed implants such as the locking compression plate, and with the use of sling assistance to protect the contralateral limb from the development of laminitis and to add stress protection of the repaired limb, it may be possible to successfully repair simple, mildly comminuted or oblique midshaft tibial fractures in adult horses. However, prognosis is poor to grave, because even with double-plating or triple-plating techniques, implant or bone failure is common and fixation usually fails during anesthetic recovery even with a pool recovery system. Given the extremely poor prognosis,

Fig. 45-1 • Lateromedial radiographic image of an adult equine tibia. There is a typical comminuted tibial fracture. The prognosis is grave and the horse should be humanely destroyed.

transportation of a horse with a flail leg should be avoided. Most horses should be immediately destroyed.

Tibial Fractures in Foals

Suckling and weanling foals with displaced, comminuted tibial fractures have a reasonable prognosis for salvage, and some become performance horses and racehorses. The size of the foal is critical, and complications in those heavier than 225 to 325 kg may be similar to those in adult horses. Most foals with tibial fractures sustain kick trauma from mares or have other accidents.

Proximal Physeal Tibial Fractures

Salter-Harris type II fractures occur in sucklings, weanlings, and rarely in yearlings. These fractures result in acute-onset lameness and swelling of the proximal, medial aspect of the crus and stifle. Within 1 to 3 days, foals are often weight bearing and may be surprisingly comfortable. Radiographs reveal a simple Salter-Harris type II fracture with a lateral metaphyseal component (Figure 45-2). Occasionally, mild

comminution exists laterally. Foals with minimal displacement can be managed conservatively, but progressive displacement, as evidenced by valgus deformity, usually occurs. Foals should be treated surgically. Many methods have been used, but the most stable repair is a medial approach in which either a T plate or two short dynamic compression plates are applied by using 5.5-mm cortex bone screws in the epiphyseal component. A long metaphyseal component can be engaged using screws placed in lag fashion. The tension side of the proximal aspect of the tibia is medial, and the T plate should be applied in this location. Because the soft tissue covering is minimal, chronic drainage from the wound is common until the plate(s) is removed. Prognosis for life is good to excellent and for soundness is fair to good. Prognosis for racing is not established, and sequelae from differences in limb length are unknown, but racing is not out of the question.

Middiaphyseal Tibial Fractures

Similar considerations for degree of comminution, location of fracture, and whether the site is open or closed apply to foals and adult horses, but in foals prognosis associated with repair is considerably better than in adults. Foals with closed, midshaft, transverse, or oblique fractures with minimal comminution are the best surgical candidates, but successful repair of those with comminution has been achieved (Figure 45-3). Foals with open fractures that are associated with a small wound and minimal contamination are also surgical candidates. A cranial approach is used to place two dynamic or locking compression plates on the craniolateral and craniomedial aspects, and additional screws are used to repair loose fragments. In a retrospective study of nine foals whose injuries were repaired in this manner, results were considered excellent in six and good or fair in two.¹¹ Additional stability can be achieved using locking compression plates, but success was reasonable with older style of implants. If fractures heal, implants should be removed, and if contralateral angular deformity does not develop, prognosis for racing should be fair to good.

Distal Physeal Fractures of the Tibia

Distal physeal fractures of the tibia do occur but are rare. Acute severe lameness, swelling, and angular and rotational deformity of the limb are present. Salter-Harris type II fractures are most common, but the small size of the epiphysis complicates surgical repair. Substantial tibial shortening can be expected, and prognosis is poor.

Tibial Malleolar Fractures

Medial malleolar fractures are rare but occasionally occur from trauma and may be associated with substantial collateral ligament injury. When collateral ligament injury is minimal, fragments can be removed arthroscopically, but visibility can be difficult without proper instrumentation. After fragments are removed, the arthroscope can usually be advanced to the plantar pouch. Prognosis is good in horses without substantial collateral ligament damage and tarsocrural instability. However, if there are additional loose fragments within the joint, this may indicate further damage of the tarsocrural joint.

See Chapter 44 for a discussion of lateral malleolar fractures.

Fig. 45-3 • **A**, Preoperative and **B**, postoperative radiographic images of a 2-month-old Standardbred foal with a diaphyseal tibial fracture.

Tibial Tuberosity Fractures

Direct trauma causes tibial tuberosity fractures, which occur most often in field hunters and jumpers. Fractures are usually nonarticular and can vary in length, width, and depth. In most horses with injuries that are managed conservatively, fractures heal functionally but without radiological evidence of union. In a retrospective study surgical repair of nonarticular fractures in six horses resulted in a successful outcome.¹² Large fractures involving the femorotibial joint surfaces can be repaired, but surgical repair is not necessary in most horses and can be associated with catastrophic fracture of the tibia if occult fracture lines are not recognized and implant failure occurs¹³ (see Figure 46-12). In one study, 10 of 14 horses with nonarticular tibial tuberosity fractures that were managed conservatively were sound, and horses performed at the expected level¹⁴ (Figure 45-4). If fractures are repaired rather than simply having screws placed across the fracture line, a tension band technique such as a short plate and screws or a combination of screws and wire should be used.

Enostosis-like Lesions of the Tibia

Enostosis-like lesions of the tibia are diagnosed by scintigraphic and radiological examinations. These lesions can be a cause of chronic, mild hindlimb lameness, or in the TB (rarely STB) racehorse they occasionally cause acute pronounced lameness mimicking that seen with a tibial stress fracture.

Osteochondroma of the Tibia

Osteochondroma of the tibia is a rare radiological finding in the distal, caudal aspect of the tibia and may be incidental or may cause tarsal tenosynovitis. I have seen one adult horse with osteochondroma that as a foal had

Fig. 45-4 • Lateromedial radiographic image of the proximal aspect of the tibia in a horse with chronic lameness and fracture of the tibial tuberosity. Conservative management of this horse resulted in a successful outcome, although radiological evidence of fracture union was never achieved.

repair of a tibial fracture. The condition has rarely been reported.¹⁵

Osseous Cystlike Lesions of the Proximal Aspect of the Tibia

Osseous cystlike lesions of the proximal aspect of the tibia are unusual, may be the result of osteochondrosis, and frequently communicate with the lateral femorotibial joint (see Figure 23-3) (Figure 45-5). There may be concomitant osteochondrosis lesions involving the distal aspect of the

Fig. 45-5 • Lateromedial (**A**) and caudocranial (**B**, lateral is to the left) digital radiographic images of a 3-year-old Standardbred gelding with a multiloculated osseous cystlike lesion and increased radiopacity of the proximal lateral tibial epiphysis (arrows). Intraarticular photographs are shown in Figure 23-3. This horse underwent arthroscopic surgical debridement using a cranial approach through the femoropatellar joint and septectomy.

lateral femoral condyle. Some adult horses develop radiolucent changes caused by osteoarthritis, but in these horses osseous cystlike lesions are acquired, not developmental. Some adult horses develop sudden-onset lameness associated with a well-established osseous cystlike lesion that was previously asymptomatic with no evidence of primary osteoarthritis. Clinical signs are similar to those in horses with other subchondral bone cysts or osseous cystlike lesions of the femorotibial joint, but lameness is often pronounced in adult horses with osteoarthritis. In most horses with osseous cystlike lesions involving the lateral femorotibial joint, curettage is difficult without elevating or severing the lateral meniscus. Some of these horses respond to conservative management and intraarticular injections of hyaluronan and corticosteroids. Intralesional injection with corticosteroids has also been reported. In horses with acquired osseous cystlike lesions related to osteoarthritis, the lesion is usually medial and prognosis is poor because cartilage damage of the proximal tibial condyle and distal medial femoral condyle is usually severe. One study described 12 horses with osseous cystlike lesions. In six the lesions were believed to be the result of osteochondrosis, and three of the six horses that received surgical debridement became athletes. Only two of six horses in which osseous cystlike lesions

were caused by osteoarthritis returned to work after surgery.¹⁶ Often, location precludes complete surgical debridement because cysts most commonly occur in the midportion of the proximal aspect of the tibia under the lateral meniscus. Prognosis worsens when the cyst cannot be completely debrided, there is concomitant involvement of the distal aspect of the femur, there is deterioration or tearing of the lateral meniscus, or there is substantial osteoarthritis.

Osseous Cystlike Lesions of the Distal Aspect of the Tibia

Osseous cystlike lesions of the distal aspect of the tibia are rare injuries and appear to be acquired as the result of trauma or stress-related bone injury. I have seen osseous cystlike lesions in this location in a jumper and a STB racehorse. In both horses, there was acute-onset lameness and tarsocrural effusion. However, such lesions can be present in the absence of effusion. Scintigraphic examination revealed focal, moderate-to-intense IRU of the distal aspect of the tibia. Horses were rested and later performed at a level similar to preinjury level. Computed tomography was useful in elucidating the lesion in other horses (see Chapter 20).

Phyinitis of the Distal Tibia

Phyinitis of the distal tibia is discussed in Chapters 57 and 128.

Fibular Fractures

Authentic fibular fractures occur rarely and are often fortuitously diagnosed scintigraphically or radiologically when images are obtained in horses with undiagnosed hindlimb lameness or in those with suspected tibial stress fractures. Fractures occur either proximally or in the mid-diaphyseal region and can appear as a chronic nonunion fracture with bulbous proliferation on each side of the fracture. There can be numerous apparent fibular fractures, and the condition can occur bilaterally. Proliferation likely existed before onset of clinical signs. Horses with midshaft fibular fractures have a large, nearly intact fibula that may predispose to fracture, but a causal relationship between this anatomical finding and fracture has not been established. Often, scintigraphic examination reveals focal IRU at the fracture site and sometimes diffuse IRU in the fibula peripheral to the fracture (Figure 45-6). The entire limb should be evaluated carefully to exclude another site of pain causing lameness. In a Warmblood jumper I observed a focal area of intense IRU of the midfibula that appeared radiologically like a large, chronic nonunion, but moderate hindlimb lameness abated after high plantar analgesia, and suspensory desmitis was the bona fide source of pain. Occasionally there is focal IRU involving both the most proximal aspect of the fibula and the immediately adjacent tibia that may reflect trauma to their articulation. Verification of this as a cause of pain and lameness is difficult. I have seen horses—three TB racehorses and one STB racehorse—with authentic fibular fractures that were discovered during scintigraphic examination. Horses were examined for poor racing or training performance or undiagnosed or high-speed hindlimb lameness and were sound with rest (see Figure 45-6).¹⁷ Four months' rest is recommended, but in horses in which lameness persists, segmental fibular osteotomy remains a potential surgical approach. The entire limb should be evaluated carefully to exclude another site

Fig. 45-6 • A, Lateral (left) and caudal (lateral is to the left) delayed phase scintigraphic images of a 4-year-old Standardbred racehorse that underwent bone scintigraphy for undiagnosed left hindlimb lameness. Focal, intense increased radiopharmaceutical uptake (IRU) of the left fibula (*large arrows*) is diagnostic of fracture. In the lateral image, focal IRU could easily be confused with a tibial stress fracture, but in the caudal image IRU is clearly in the fistula. There is diffuse mild-to-moderate IRU in the fibula distal to the fracture site (*small arrows*), indicating that abnormal bone modeling exists peripheral to the fracture site. **B,** Craniolateral-caudomedial oblique plain radiographic image showing a midshaft fibular fracture (*arrow*) and bony enlargement of the fibula proximal and distal to the fracture site. A large, nearly intact fibula is present.

of pain causing lameness. Six horses with proximal fibular fractures made complete functional recoveries; horses were sound within 3 months, but a fracture line persisted radiologically until 4 to 6 months after the injury.⁸

Nonossifying Fibromas of the Proximal Tibia

A yearling TB filly with rare, nonossifying fibromas of both tibias was examined because of kyphosis of the lumbar spine and a stilted hindlimb gait.¹⁸ Radiographs revealing radiolucent defects and sclerosis of the proximal tibial epiphyses and scintigraphic images published in the case report¹⁸ look similar to those of horses I have seen with multiloculated proximal tibial osseous cystlike lesions thought to be a form of osteochondrosis (see Figure 45-5).

Tumors

Hemangiosarcoma occurs rarely in the proximal aspect of the crus. Firm, slow-growing, subcutaneous, soft tissue masses without bone involvement are composed of multiloculated areas of hemorrhage and can be excised without recurrence. It was reported that a fibrosarcoma of the distal, caudomedial aspect of the crus just above the tarsus was resected and recurrence was not seen at 1½ years after surgery.¹⁹

Soft Tissue Injuries of the Crus

Fibularis tertius injury in foals and adult horses is discussed in Chapter 80, and gastrocnemius tendonitis is discussed in Chapter 80. Stringhalt is discussed in Chapter 48.

Chapter 46

The Stifle

John P. Walmsley

ANATOMY

Developmental Anatomy

The seven centers of ossification in the stifle of the foal are the metaphyses of the femur and tibia, the distal

femoral epiphysis, the proximal tibial epiphysis, the patella, the tibial tuberosity (the apophysis), and the fibula. The proximal tibial physis closes at about 2½ years of age. The tibial apophyseal-epiphyseal physis closes by 1 year of age. The apophysis does not fuse with the metaphysis until 3 years of age. This apophysis is an important radiological feature in a young horse and can be mistaken for a fracture. The distal femoral physis closes by about 2½ years of age. In young foals, the margins of the femoral trochleas and the patella are irregular for the first 3 months of life because of incomplete ossification. The fibula is not evident radiologically until about 2 months of age, and a high percentage of adult horses have one and occasionally up to three horizontal radiolucent lines in the fibula distal

to its head. These should not be confused with fracture lines.¹

Reciprocal Apparatus

The reciprocal apparatus has an important influence on the action of the stifle. Extension of the joint exerts a pull on the superficial digital flexor tendon, which originates in the supracondyloid fossa of the femur and is mostly tendinous. Because this flexor tendon has an insertion on the calcaneus, the hock must extend simultaneously with the stifle. On the cranial aspect of the stifle, the fibularis (peroneus) tertius, also a tendinous structure, originates in common with the long digital extensor tendon between the lateral trochlea and the lateral condyle of the femur.² The fibularis tertius passes through the extensor sulcus in the lateral part of the tibial head, associates closely with the deeper tibialis cranialis muscle, and inserts on the third tarsal and third metatarsal bones and the fourth tarsal bone and calcaneus. Flexion of the stifle necessitates flexion of the hock because of the action of the fibularis tertius.² Weight bearing is achieved without much muscular effort by the parapatellar fibrocartilage of the medial patellar ligament hooking over the medial femoral trochlea by contraction of the quadriceps femoris. The patella is released by contraction of the quadriceps femoris, combined with the lateral pull of the tensor fascia latae and biceps femoris.

Femoropatellar Joint

The articulation between the patella and the trochleas of the femur forms the femoropatellar articulation. The patella has three straight ligaments. The medial patellar ligament attaches to the medial border and the distal aspect (apex) of the patella through the parapatellar fibrocartilage. Arthroscopically the ligament can be viewed beneath the joint capsule. Distally the medial patellar ligament attaches medial to the groove on the cranial aspect of the tibial tuberosity. The middle patellar ligament originates on the cranial part of the patella just proximal to the apex and inserts in the distal part of the groove of the tibial tuberosity. The lateral patellar ligament extends from the lateral aspect of the patella to the lateral part of the tibial crest. The biceps femoris has a tendon of insertion on this ligament.³ Femoropatellar ligaments also reinforce the joint capsule medially and laterally, the lateral ligament being the more distinct.

The medial trochlear ridge of the femur is larger and more rounded than the lateral trochlear ridge and articulates with the medial part of the patella and the fibrocartilage of the medial patellar ligament. The joint capsule has a large suprapatellar pouch and inserts abaxially on the trochlear ridges forming lateral and medial recesses, the lateral being the smaller. A large fat pad is cranial to the joint capsule, proximal and distal to the patella. In my experience, most horses have a slitlike opening into the respective femorotibial joints at the distal end of the medial trochlear ridge and frequently the lateral trochlear ridge as well. Latex passed from the femoropatellar to the medial femorotibial joint in 60% to 65% of horses and in the reverse direction in 80% of horses.³ Diffusion of mepivacaine between all the compartments may occur in about 75% of horses.⁴

Femorotibial Joints

The medial and lateral femorotibial joints are separate compartments, which are divided by an intact median septum in a healthy joint. However, they may communicate after trauma.⁵ The crescent-shaped, fibrocartilaginous medial and lateral menisci lie between the respective femoral and tibial condyles to form a congruent articulation.² Both are attached to the tibia, cranial to the intercondylar eminences, by cranial ligaments. The medial ligament wraps around the cranial aspect of the medial intercondylar eminence before inserting on the tibia. The medial meniscus is also attached caudally to the medial intercondylar eminence by the caudal ligament, which can be seen arthroscopically in the caudal part of the medial femorotibial joint. The lateral meniscus attaches caudally to the popliteal notch of the tibia and through the strong meniscofemoral ligament to the caudal part of the intercondylar notch of the femur. Only the cranial and caudal poles of the menisci can be viewed arthroscopically because of the close apposition of the tibia and femur, but the respective cranial ligaments are clearly visible. During flexion the menisci slide caudally, and during extension they slide cranially.

The cranial cruciate ligament has its tibial attachment cranial to the medial intercondylar eminence and its femoral attachment in the lateral part of the intercondylar notch. The cranial cruciate ligament lies beneath the median septum and usually cannot be directly viewed arthroscopically without removing the septum. A better view is often gained from the lateral compartment. The caudal cruciate ligament originates in the popliteal notch of the caudal aspect of the tibia and runs proximally, medial to the cranial cruciate ligament, to insert cranially in the intercondylar notch of the femur.⁶ The ligament can be viewed beneath the septum in the cranial and caudal medial compartment of the femorotibial joint. In the dog, the cranial cruciate ligament is under tension during extension of the femorotibial joint,⁷ and this may be so in the horse.

The collateral ligaments both originate proximally on the respective epicondyles of the femur. The medial collateral ligament inserts distally on the tibia distal to the medial condyle and has attachments to the medial meniscus. The lateral collateral ligament lies over the popliteal tendon and inserts distally on the head of the fibula. The popliteal tendon originates close to the lateral collateral ligament on the femur and courses distally and caudally, in close apposition to the femoral condyle, to a triangular area of insertion on the proximal caudal aspect of the tibia. The tendon is viewed arthroscopically in the cranial aspect of the lateral femorotibial joint and also in the caudal part, which it effectively divides, limiting the arthroscopic accessibility. The tendon of origin of the long digital extensor muscle can be followed arthroscopically in the cranial compartment of the lateral femorotibial joint from its origin on the extensor notch of the femur and is usually invested within the joint capsule, although in some traumatized joints, the tendon appears separate.⁵

DIAGNOSIS

General Considerations

The history may give an important lead to diagnosing the cause of lameness. For example, a young horse is a candidate for osteochondrosis or subchondral cystic lesions.

Acute-onset stifle lameness in a horse at pasture or during work is more likely to be a traumatic injury involving ligaments or bone. Sudden reduction of work or poor condition may predispose to upward fixation of the patella. Palpation of the patellar ligaments and the outline of the patella, collateral ligaments, long digital extensor tendon, tibial crest, and medial and lateral tibial condyles should be possible. Many horses with stifle injuries manifest no abnormalities on physical examination of the joint. If severe trauma has occurred, the whole region may be swollen, making palpation of the individual structures difficult. The horse may guard the limb so strongly that instability may not be obvious. Because of the ligamentous structures around the joint, distention is only readily palpable over the cranial aspect of the femoropatellar joint and over the medial femorotibial joint cranial to the medial collateral ligament.

Gait and Manipulative Tests

Differentiating stifle lameness in the horse by studying the gait is difficult because the reciprocal apparatus coordinates the movement of the whole limb. In my view, attributing the cause of certain gait changes to stifle pain is not possible. Some horses with stifle pain may carry the stifle slightly abducted, but this is not specific. A careful analysis of the whole limb is required to establish the site of pain causing lameness. Other gait changes that may be seen with stifle lameness, but which are also not specific, are a reduced cranial phase of the stride and a reduced flexion of the limb in flight. Many horses with stifle pain dislike going downhill. Horses with delayed release or upward fixation of the patella tend to avoid fully extending the limb and appear to have a crouching gait. Flexion of the upper limb exacerbates lameness in horses with stifle pain, and abduction of the limb may be resented. When performing proximal limb flexion tests, holding the limb at midmetatarsal level, rather than by the foot, helps to differentiate between upper and lower limb pain.

Three specific manipulative tests have been described for the stifle. These are the cruciate test, collateral ligament test,⁸ and patellar displacement test. Most horses with clinically significant stifle pain resent these tests, which makes the tests difficult to perform and to interpret. All manipulation or flexion tests should be done on the contralateral limb first. For the cruciate test, the affected limb should be weight bearing. The head of the tibia is pushed caudally and then released 5 to 10 times before trotting the horse. Laxity is supposed to be appreciated and lameness exacerbated if severe cruciate injury exists. I have never found this test effective. Pain in the affected joint provokes strong guarding by the horse so that the procedure is impossible to perform. The medial collateral ligament test involves abducting the distal limb against shoulder pressure exerted on the femorotibial joint 5 to 10 times before trotting the horse. Horses with ruptured medial collateral ligaments are so painful and instability is so great that this test is inappropriate, but it can be useful for a sprain of the ligament. The lateral collateral ligament is less often affected, but it can be tested by pulling the distal aspect of the limb medially. Lameness associated with problems with patella release may be worsened by pushing the patella proximally several times with the horse weight bearing before trotting, but again this is often an unrewarding test.

DIAGNOSTIC ANALGESIA

In many horses with low-grade stifle lameness, positive diagnostic analgesia is the only way to localize the site of pain, so it is an important test. Because diffusion of local anesthetic solution between the three joint compartments is so variable,⁴ all three must be blocked to ensure a valid test. Alleviation of lameness after analgesia of one compartment does not necessarily infer that that compartment is definitely the source of pain.

I use a 5-cm, 19-gauge needle for each joint compartment and up to 30 mL of local anesthetic solution because experience has shown that 20 mL in each compartment might be incompletely effective in a 600-kg horse. Strict aseptic procedure should be followed. Arthrocentesis of the femoropatellar joint is well tolerated and performed first. An intradermal bleb is usually unnecessary. However, an inexperienced veterinarian may find one helpful for the medial femorotibial compartment because some horses are sensitive to injection at this site. My preferred approach for the femoropatellar joint is between the middle and medial patellar ligaments. Synovial fluid is infrequently retrieved from this site unless the joint capsule is distended. If a synovial fluid sample is required, it may be retrieved more easily through a lateral approach.⁹ The lateral cul-de-sac is entered caudal to the caudal edge of the lateral patellar ligament and 5 cm proximal to the tibial condyle. The medial femorotibial compartment is entered over the medial tibial condyle between the medial patellar ligament and the medial collateral ligament. A small outpouching of the joint capsule may be palpated. The lateral femorotibial compartment is best approached just cranial or caudal to the long digital extensor tendon and close to the tibial plateau. Less space is available between the meniscus and the joint capsule in the latter approach, so the former is preferred. An improvement in lameness can be expected in 30 minutes, but the clinician is wise to allow at least 1 hour for the final assessment.

Horses with a number of conditions causing lameness in the stifle respond incompletely or not at all to intraarticular analgesia. Horses with medial or lateral collateral ligament or patellar ligament injuries may be unaffected. Horses with subchondral bone cysts in the medial femoral condyle show a variable response, ranging from resolution of lameness to little change, and analgesia can take a long time to take effect. Horses with conditions that cause severe lameness are often only partially improved by analgesia; these conditions include infections; fractures, particularly patellar and tibial crest fractures; advanced osteoarthritis (OA); and severe cruciate and meniscal tears.

IMAGING CONSIDERATIONS

Radiography

Although many stifle injuries are not associated with detectable radiological changes, radiography is usually the first imaging mode to be used once the site of pain causing lameness has been established as the stifle, or if the distal aspect of the limb has been excluded as a potential source of pain. An x-ray machine capable of producing at least 90 kV and 20 mAs is required. In larger horses, adequate definition will only be achieved with even higher-powered x-ray generators. Fast-screen film combinations can be used

particularly for caudocranial images. Using as slow a combination as possible is always worthwhile, commensurate with safe practice, to achieve the best definition on the radiograph. Large cassettes are necessary and should be held in a cassette holder with a long handle. Because of the difficulty of aligning the cassette perfectly in the standing horse, using a grid is impractical, although one can be used if the horse is under general anesthesia. Many horses dislike having cassettes placed close to the stifles, so great care must be taken with this procedure. If any doubt exists about the horse's temperament, the horse should be sedated.

Five standard images are most commonly used: lateromedial, flexed lateromedial, caudocranial, caudolateral-cranio-medial oblique, and cranioproximal-craniodistal oblique (skyline). The radiographic anatomy of the soft tissue attachments of the stifle is well described.¹⁰

Lateromedial Image

The horse should be standing naturally for this image. The x-ray beam is directed perpendicular to the stifle. The stifle is naturally rotated slightly laterally in most horses, which predisposes to the beam being directed from too far cranially. The x-ray beam should pass just proximal to and parallel to the tibial plateau. The landmark on which to target the x-ray beam is the lateral condyle of the tibia. The cassette has to be pushed as far proximal as possible, which can be difficult in a well-muscled horse or a stallion. In a well-positioned radiographic image, the femoral condyles are superimposed on each other.

Flexed Lateromedial Image

The limb is held in the farrier's position with the tibia parallel to the ground. If the stifle is held with its axial plane vertical, directing the x-ray beam perpendicular to the joint is easier. The same landmarks are used as for the standing lateromedial image. When the x-ray beam is correctly positioned, the femoral condyles are superimposed. When compared with the standing lateromedial radiographic image, the flexed image reveals a greater area of the medial intercondylar eminence of the tibia and the cranial part of the femoral condyles and also allows more complete imaging of the patella.

Caudocranial Image

The caudocranial image requires relatively high exposure factors. A key feature for correct positioning is the angle of the tibia because the x-ray beam should be perpendicular to the tibia. Placing the horse in its natural stance or with the limb slightly caudal to the contralateral limb facilitates correct alignment. The x-ray beam should divide the limb in the caudocranial plane and pass just proximal to the level of the lateral tibial condyle. The natural lateral rotation of the stifle should also be taken into account. Thus the x-ray beam is usually aimed craniodistally and cranio-laterally and meets the caudal musculature of the thigh surprisingly proximally. The correct image defines the femorotibial joint spaces and clearly images the intercondylar eminence of the tibia within the supracondylar fossa of the femur.

Caudal 30° Lateral-Cranio-medial Oblique Image

For the caudal 30° lateral-cranio-medial oblique image, the x-ray beam is directed 30 degrees from the caudocranial

plane and slightly from proximal to distal, so that it crosses parallel to the tibial plateau, which it should bisect. The main value of this image is imaging the lateral femoral trochlea, with the advantage of highlighting the medial femoral condyle, and it can be used to screen for osteochondrosis lesions and subchondral cystic lesions.

Cranioproximal-Craniodistal Oblique Image

The cranioproximal-craniodistal oblique image is a skyline image of the patella and femoral trochlear ridges and may be the only view on which a patellar fracture may be seen. In a standing horse, the limb is held in the farrier's position with the tibia horizontal. The x-ray beam is aimed along the articular surface of the patella, but it may be impeded by the horse's flank. Twisting the metatarsal region medially, which rotates the stifle laterally, sometimes allows better access to the patella. The cassette is held along the cranial proximal aspect of the tibia, and the x-ray beam is directed almost vertically. Checking the position of the patella on a previous flexed lateromedial image helps to decide on the correct beam angle. In an anesthetized horse, the leg is flexed with the horse in dorsal recumbency, and the x-ray beam is directed from distal to proximal.

The contours of the femoral trochlear ridges and the patella are irregular in young foals. In most foals this irregularity is present up to 11 weeks of age, and in 45% of foals, up to 25 weeks.¹¹ In foals older than 5 months of age, irregularity of the femoral trochleas is abnormal. Irregularity of the femoral or tibial condyles is abnormal at any age.

Ultrasonography

A substantial proportion of stifle lameness is caused by soft tissue damage; therefore ultrasonography has a potential diagnostic role in defining the injury and has several advantages over other imaging diagnostic techniques. At present, ultrasonography is the only method of assessing soft tissue injury in the stifle in a standing horse. The disadvantages are that ultrasonography requires experience to be used effectively and a good-quality ultrasound scanner with a sector and a linear array transducer is necessary. Transducer frequencies of 7.5 and 5 MHz are needed to image the cranial aspect of the stifle, but a 3-MHz transducer is required to image the caudal part of the stifle.¹²⁻¹⁵ When it becomes available, magnetic resonance imaging (MRI) is likely to be a superior imaging technique for soft tissues of the equine stifle.¹⁶ Computed tomography (CT) has already proven useful for evaluation of meniscal tears and for detection of cartilage and subchondral and trabecular bone injury.¹⁷

Ultrasonography can be valuable for differentiating joint capsule distention from extraarticular swelling. Soft tissue structures that can be imaged include the patellar ligaments, the menisci and the respective cranial ligaments, the collateral ligaments, the cranial and caudal cruciate ligaments, the menisiofemoral ligaments, the origin of the long digital extensor tendon, and the popliteal tendon. The articular cartilage and bony outline of the femoral trochlear ridges and the cranial and caudal third of the femoral condyles may also be imaged.¹²⁻¹⁵

The patellar ligaments and the collateral ligaments can be imaged longitudinally and transversely with a 7.5- to 10-MHz linear array transducer with the horse weight bearing. The middle patellar ligament is the most obvious

of the three and is a useful landmark. The femorotibial collateral ligaments can be imaged from the attachments on the distal lateral or medial femoral epicondyles to the attachments on the proximal medial or lateral aspects of the tibia, and they lie over the respective menisci.¹⁸ The menisci can also be imaged with this transducer from caudal to the medial and the lateral patellar ligaments. They appear as wedge-shaped structures of moderate echogenicity with the base of the wedge closer to the transducer. The cranial ligaments of the menisci are more easily imaged with a small convex array or sector transducer, which can be aimed more perpendicular to the meniscal ligaments and which can be more easily positioned between the patellar ligaments. The cruciate ligaments are difficult to image because aligning the transducer perpendicular to the fibers of the ligament is difficult. Only a small length of ligament can be imaged at a time, which can make interpretation equivocal. Cruciate ligaments can only be viewed with the stifle in a flexed position using a convex array or sector scanner. Useful information on the surfaces of the femoral trochlear ridges and condyles can be obtained. The condyles are imaged with the stifle in a flexed position, and this can be helpful in diagnosing subchondral bone cysts.¹⁹ From caudal, a sector transducer is preferable for imaging the caudal cruciate ligament and the menisofemoral ligaments, and a 3-MHz transducer is necessary in large horses.¹³

Scintigraphy

Scintigraphy has been used on horses for more than 30 years, but little published evidence assesses its specificity and sensitivity for conditions of the stifle. A recent study of 16 horses indicated moderate to high sensitivity of scintigraphy for detection of meniscal damage, cruciate ligament injury, or articular cartilage pathology in the stifle using arthroscopy as the gold standard, but specificity was low, indicating a high risk of false-negative results.²⁰ For most stifle conditions, scintigraphic findings are variable, and although positive findings are obviously helpful, negative findings can also add useful information. The clinical significance of any scintigraphic result should be confirmed as exhaustively as possible by other tests, particularly diagnostic analgesia because false-positive results also occur. In the normal adult stifle, the caudal aspect of the tibial epiphysis often has highest uptake of radiopharmaceutical.²¹

Nuclear scintigraphy is most consistently valuable in diagnosing incomplete avulsion fractures associated with the stifle.^{22,23} However, although positive results may be obtained within 24 hours of injury, in some horses at least 3 days must elapse before clinically significant increased radiopharmaceutical uptake (IRU) occurs. Subchondral cystic lesions that cause lameness may be scintigraphically positive or negative (Figure 46-1). The lesions are more likely to be detected in older horses, using a caudal image, than in an immature horse with high background activity. Absence of radiopharmaceutical uptake was thought to be the result of osteoclasts being the dominant cells in certain stages of the condition.^{24,25} However, in the Editors' experience the majority of subchondral cystic lesions do have focal IRU. Although scintigraphy has been used to assess osteochondrosis in people,²⁶ bone scan findings are not well documented in horses. I have seen positive and negative scintigraphic results associated with clinically

Fig. 46-1 • Lateral delayed (bone) phase scintigraphic image of the right stifle of a 9-year-old Thoroughbred cross gelding. There is focal increased radiopharmaceutical uptake in the distal femoral condyle (arrow). A subchondral bone cyst in the medial femoral condyle thought to be causing lameness was seen radiologically.

significant osteochondrosis of the lateral femoral trochlea. Soft tissue injuries of the stifle are often scintigraphically negative, but in my experience IRU can occasionally be encountered in these horses, especially in association with enthesopathy.

Scintigraphy is certainly a useful tool as a diagnostic aid for lameness in the stifle and can be useful for evaluating the bone activity of lesions. Occasionally horses may respond positively to intraarticular analgesia, but no clinically significant abnormalities are found on radiography, ultrasonography, and arthroscopy. IRU in the stifle may be the only finding. Making a definitive diagnosis in these horses is difficult, although conceivably subchondral bone pain may be a possible cause of the lameness. One should bear in mind that many stifle conditions are negative scintigraphically. Conversely, the joint may be scintigraphically positive when the cause of lameness is elsewhere in the limb.

ARTICULAR DISEASES

Femoropatellar Joint

Osteochondrosis

Osteochondrosis has been recognized in horses for more than 50 years and is an important cause of stifle lameness in young horses. The exact cause of the disease is still not well defined, but several factors are known to influence its development. Adequate dietary copper is important. Mare's milk is relatively low in copper, and because the foal relies on copper stored in its liver during late pregnancy, it will be deficient if the mare's diet contains insufficient copper. The zinc/copper ratio is also important because

zinc inhibits the absorption of copper.²⁷ Foals on high-energy diets are more prone to the disease.²⁸ Insufficient or excessive exercise and trauma may be factors that influence the development of the disease. Genetic factors may predispose to osteochondrosis in the hock of Swedish Standardbreds (STBs).²⁹ Large, fast-growing males are more susceptible. Osteochondrosis is most frequently seen in Thoroughbreds (TBs) and Warmbloods. The lesions probably develop in the first 7 months of life,³⁰ but sometimes clinical signs may not be manifest until the horse is brought into work. In the sports horse this may be as late as 5 years of age or even older when a mild to moderate lameness may develop as the horse begins more serious work. In my experience, surprisingly severe lesions can remain undetected until this time. Lesions are most commonly seen on the lateral trochlear ridge of the femur³¹ but do occur on the medial trochlea, intertrochlear groove, and patella and are often bilateral.

Signs and Diagnosis

Osteochondrosis may be present asymptotically. Lameness is often acute in onset and varies from a subtle gait deficit to marked lameness. Lameness is often more acute in onset and more severe in foals and young yearlings than in older horses. Distention of the femoropatellar joint capsule is often present and can be severe, especially in foals and yearlings. Gluteal muscle atrophy is seen in horses with severe lesions. Flexion tests are mostly positive. Synovial fluid may be hemorrhagic, but it is often normal. Intraarticular analgesia of the femoropatellar joint should improve lameness. However, in mature horses lameness may be mild, with no effusion and a poor response to intraarticular analgesia. In such horses arthroscopic evaluation often reveals an extensive area of cobblestone-like cartilage, with extensive fibrillation over a large portion of the lateral trochlea of the femur. This cartilage is often well adherent to the subchondral bone and little clinical benefit is derived from surgery.

Radiological changes include the following: no detectable signs, slight loss of contour or loss of outline of the lateral trochlear ridge, irregular defects in the trochlear ridge, radiodense fragments within the defect (Figure 46-2), round radiopaque bodies loose in the joint, and more rarely, irregularities on the patellar apex or the medial trochlear ridge.^{1,32,33} Lateromedial and caudolateral-cranio-medial oblique images are the most useful projections. Horses with radiological lesions do not always show lameness.^{25,27} Some horses have no detectable radiological abnormalities, but osteochondrosis lesions are diagnosed on arthroscopic examination. Lesions without fragmentation in young foals may resolve with time,^{32,33} but many progress.³⁴

Treatment

Conservative management, with confinement and correction of dietary imbalances, and arthroscopic debridement of the lesions are the main treatment options. Conservative management is appropriate for horses with mild lesions. Because of the insensitivity of radiological evaluation of osteochondrosis lesions, an argument can be made for arthroscopic examination of most horses with lesions seen radiologically or persistent femoropatellar effusion and lameness that fails to respond to conservative treatment.³⁵

Fig. 46-2 • Lateromedial radiographic view of the femoropatellar joint of a yearling Thoroughbred colt. There is a large irregular defect in the subchondral bone of the lateral trochlear ridge containing several radiodense fragments.

Arthroscopic examination would ensure that horses with radiologically silent cartilage lesions are treated effectively. OA can also be evaluated. For horses with fragmentation and clinically significant radiolucent defects of subchondral bone, arthroscopic surgery is probably the treatment of choice.³¹ In my opinion, more caution is required when treating foals arthroscopically because some foals with large lesions seen radiologically are found to have intact cartilage at arthroscopy. Debridement of such lesions can leave unacceptably large deficits in the lateral trochlear ridge. Reattaching these cartilage flaps with polydioxanone pins may be a more appropriate treatment and has shown good results with seven of nine foals achieving athletic use.³⁶

A variety of lesions are seen arthroscopically. The articular cartilage may appear intact, but if probed, large flaps may lift from the subchondral bone. Large defects on the lateral trochlear ridge may contain nodules of mineralized cartilage, which are readily removed, and often large tufts of fibrillated cartilage are associated with the lesion. The exposed subchondral bone is frequently soft and crumbly. Extensive areas of fibrillated cartilage over the adjacent lateral trochlear ridge and the opposing patella are often present in older horses.⁵ Loose cartilage should be removed, and the lesion should be curetted to healthy subchondral bone, which is a source of pluripotent cells. The cartilage perimeter should be vertical to allow better attachment of tissue regrowth.³⁷ Thorough lavage to remove all debris, particularly of the suprapatellar pouch, at the completion of surgery is essential. Six weeks of stable rest with daily handwalking after 2 weeks is recommended postoperatively. The horse should then be left for another 4 to 5 months at pasture before returning to work.

Prognosis

Mild lesions in foals were shown to heal with conservative management.^{32,33} For foals with more severe lesions, better results were reported with arthroscopic debridement.³¹ Sixty-four percent of 161 horses were able to perform

athletically. In this series, treatment of older horses and those with mild to moderate lesions was most successful, which has also been the experience in my practice. The presence of extensive secondary articular cartilage fibrillation did not have a significant effect on the outcome in horses more than 2 years of age.⁵

Upward Fixation of the Patella and Delayed Patellar Release

Upward fixation of the patella occurs when the stifle subtends an angle of approximately 145 degrees and the medial patellar ligament hooks over the medial trochlea of the femur, thus locking the reciprocal apparatus with the limb in extension. The condition is more common in horses with a straight hindlimb conformation with a stifle angle nearer 140 degrees (in the normal horse the angle is about 135 degrees), so that only a small degree of extension is required for upward fixation to occur.³⁸ Upward fixation is not a luxation of the patella, despite being commonly described as such. Predisposing straight hindlimb conformation or the condition itself may be hereditary.³⁹ Upward fixation of the patella is more commonly seen in young horses and ponies, especially if they are in poor condition, when weak thigh musculature fails to release the patella. Upward fixation can occur in older horses after trauma to the stifle region, is most frequently manifest when the affected horse is stabled, and sometimes occurs in fit horses that are suddenly given box rest. Lameness may develop in horses with more severe or long-standing lesions. I recognize delayed patellar release as a condition in which delayed release of the patella occurs, without complete upward fixation, and which presumably is a less severe form of the disease.

Signs and Diagnosis

A horse with upward fixation of the patella stands with the hindlimb locked in extension with the fetlock flexed (Figure 46-3). The leg releases with a snap, usually unaided,

Fig. 46-3 • Three-year-old Welsh Cob gelding with the typical stance of upward fixation of the patella in the right hindlimb.

but occasionally the horse needs assistance. Some horses merely show intermittent delayed release of the patella, especially when turned toward the affected limb. This can be mistaken for stringhalt. Delayed patellar release is manifested by a catching of the patella as the limb is protracted, usually as the horse moves off. Delayed release of the patella may be evident as a rather jerky movement of the patella when the horse moves over in the stable or as it decelerates from canter to trot or trot to walk. Horses in which the condition is chronic develop stifle soreness and may be resistant to work, especially in deep going. If the condition is more serious, horses try to avoid extending the hindlimbs while walking uphill or downhill. Femoropatellar effusion may be present. Diagnosis may depend on the history and the owner's description if the horse does not lock the patella during the examination. Locking the patella manually may be possible by pushing it proximally, although this can be difficult and is resented by many horses. A careful search should be made for concurrent stifle disease such as osteochondrosis or soft tissue injury, and the site of any lameness should be confirmed by diagnostic analgesia. Radiographic examination of both stifles is prudent because any pathological condition caused by upward fixation or concurrent with it affects treatment and prognosis.

Treatment

For a horse that has the patella locked, pushing the patella medially and distally and backing the horse is recommended but difficult to do. Pulling the limb forward with a side line may provide relief. If the upward fixation of the patella is intermittent and not causing lameness, a conditioning program should be undertaken. This includes an exercise regimen, the administration of anthelmintics, an increased plane of nutrition, and dentistry as appropriate for each horse. The exercise regimen depends on the specific circumstances for each horse. Daily lunging should be instituted to a level that is appropriate for the age and type of horse. Stable rest is usually contraindicated, and turning the horse out to pasture as much as possible is preferable. Immature horses should be allowed time to outgrow the problem. Injection of counterirritants containing iodine into the medial and middle patellar ligaments has been used at this stage of the disease.⁴⁰ Horses with delayed patellar release require the same management.

Because of potential complications, which include fragmentation of the patella and lameness, surgery is only indicated when the following criteria have been fulfilled:

1. Upward fixation of the patella persists despite an appropriate conditioning program.
2. Lameness has developed because of the disease.
3. The condition in an immature horse does not resolve as the horse matures.

The surgery can be performed under local anesthesia in the standing horse.⁴¹ A small incision is made over the distal part of the medial patellar ligament. I find that minimizing the incision length seems to reduce the incidence of postoperative swelling. A curved Kelly forceps is then advanced caudally under the ligament, developing a path for a blunt-ended bistoury. The bistoury is passed until its end can be palpated caudal to the medial patellar ligament, before the ligament is severed close to its tibial insertion.

Stringent asepsis should be observed. Once the ligament is severed, the border of the tendon of the sartorius muscle is palpable caudally. Some surgeons prefer to perform this surgery with the horse under general anesthesia, which allows for complete asepsis: the ligament can be exteriorized before severing, and the fascia overlying the ligament can be sutured before skin closure.

An alternative treatment involving numerous splitting incisions in the medial patellar ligament was described and was successful in four horses and three Shetland ponies, but only two horses were followed beyond 5 months.⁴²

Postoperatively I prefer to confine the horse for 2 months to allow the patella to settle in its new position in the intertrochlear groove. Handwalking can be introduced during the second month.

Prognosis

A substantial number of horses respond to conservative treatment. Occasional recurrences happen if the horse has enforced stable rest, but many grow out of the condition. After surgery and in the absence of degenerative changes in the joint, the horse should return to normal use, although some appear to have a slightly restricted gait. Recurrence of the condition is unusual. Some fibrous thickening is palpable at the surgical site for many years in most horses and indefinitely in some horses. Clinically significant complications including lameness, local swelling, fragmentation of the patella, and fracture of the patella were reported.⁴³⁻⁴⁸ Fragmentation of the patella was produced after experimental medial patellar desmotomy.⁴⁶ If fragmentation causes lameness, horses can be managed arthroscopically with good results.³³ In my experience, up to 30% of horses have minor fragmentation of the patella, without clinical signs, after medial patellar desmotomy. Injury of the middle patellar ligament can also occur secondary to medial patellar desmotomy.^{49,50}

Fragmentation of the Patella

Fragmentation of the patella is generally considered to be a sequela to medial patellar desmotomy or to be associated with upward fixation of the patella, and it is manifested by fragmentation of cartilage and bone off the apex of the patella.^{43,46,48,50} This condition is not chondromalacia of the patella, which could be a form of osteochondrosis, and has not been specifically reported in horses. If the condition follows desmotomy, clinical signs can appear from 3 weeks to more than 12 months postoperatively. Horses can develop fragmentation within a few weeks of surgery without clinical signs.⁵ Medial patellar desmotomy was performed experimentally in 12 horses, and of these eight developed fragmentation.⁴⁶ The lesions may be caused by instability of the patella after medial patellar desmotomy.

Signs and Diagnosis

Lameness varies from a stiff hindlimb action to an obvious lameness. Flexion is resented and worsens the lameness. Synovial effusion is common, and excessive fibrous tissue reaction may be present at the surgical site. Radiologically, small bone fragments are present close to the apex of the patella (Figure 46-4), often combined with radiolucent defects of subchondral bone and roughening or spurring of the distal cranial aspect of the patella.

Fig. 46-4 • Lateromedial radiographic image of the stifle of a 7-year-old Thoroughbred cross gelding that had previously had a medial patellar desmotomy to treat intermittent upward fixation of the patella. The apex of the patella is fragmented (arrow).

Treatment

Arthroscopic debridement is indicated. The lesions are most commonly on the lateral surface of the apex of the patella and may be partly obscured by synovial villi; therefore a careful arthroscopic examination should be performed before deciding on the site of the instrument portal. Debridement of the lesion to healthy subchondral bone is required.

Prognosis

The prognosis for athletic function is reasonable, although some horses appear to have a slightly stiff hindlimb action because of the original medial patellar desmotomy. Ten of 15 horses returned to athletic use.⁴³ In my experience, the incidence of the condition has decreased in the past 8 years, which may be because fewer patellar desmotomies are performed or because more care is taken during convalescence.⁵ However, the condition still occurs despite appropriate rest after medial patellar desmotomy.⁵⁰

Luxation of the Patella

Lateral luxation of the patella in the foal is considered to be an inherited condition caused by a recessive gene.⁵¹ Luxation in an adult horse is likely to be traumatic in origin.³⁸ Because the medial trochlear ridge of the femur is largest, only severe trauma induces medial displacement of the patella. Hypoplasia of the lateral trochlea of the femur is often present in association with lateral luxation of the patella,³⁹ but the condition also occurs in foals with apparently normal conformation.⁵¹ Luxation is most common in miniature breeds but has been reported in STBs, TBs, and an Arabian foal,⁵²⁻⁵⁴ and I have seen it in a Welsh Cob.⁵

Signs and Diagnosis

The condition may be unilateral or bilateral and has been graded as follows:

- Grade 1: The patella can be manually luxated but readily reduces itself.

- Grade 2: The patella is usually in place but luxates intermittently.
- Grade 3: The patella is usually luxated but can be manually relocated.
- Grade 4: The patella is continuously luxated and cannot be relocated.⁵³

Severely affected foals are unable to extend the stifle and stand in a characteristic crouching position. If less severe, the condition may not be obvious clinically, but horses are usually reluctant to flex the stifle and have a stiff gait in the affected limb. Some horses show little evidence of the disease until degenerative changes provoke lameness. I have seen a TB yearling with severe osteochondrosis of the lateral trochlear ridge, which led to a diminution of the ridge and allowed the patella to luxate laterally. One of the Editors (MWR) has seen numerous STB foals with severe osteochondrosis of the lateral trochlear ridge of the femur and patellar luxation. Lateromedial, cranioproximal-craniodistal oblique, and caudocranial radiographic images are the most useful to ascertain the position of the patella and to evaluate the trochlear ridges.

Treatment

Lateral release and medial imbrication of the femoropatellar compartment are necessary to maintain the patella in the intertrochlear groove.⁵²⁻⁵⁴ Both lateral release and medial imbrication appear to be important. Recession sulcoplasty is valuable in the presence of hypoplasia of the lateral trochlear ridge of the femur.⁵⁴

Prognosis

Poor success can be expected with surgery in the presence of OA, large osteochondrosis lesions, and in larger horses. In foals there is a moderate prospect of achieving athletic function. Aggregating the results from the three reported case series, the patella maintained its position postoperatively in eight of 11 foals.⁵²⁻⁵⁴ Breeding from affected horses should be discouraged.

Osteoarthritis

Any injury to the femoropatellar joint can potentially cause OA. The injury could be simple trauma or result from any of the previously mentioned conditions if they have caused irreversible changes.

Signs and Diagnosis

The clinical signs depend on the cause and severity of the condition. Lameness is usually persistent, and chronic joint distention may be present. If osteochondrosis is responsible for OA, radiological changes typical of chronic osteochondrosis are likely to be present (see page 536). Cartilage fibrillation, ranging from focal tufting to widespread involvement of the femoral trochlear or patellar articular cartilage, may be seen arthroscopically, and full-thickness defects of the articular cartilage may be present in more severely affected horses.

Treatment

Initially treatment depends on the inciting condition and is described in the appropriate sections. However, once chronic osteoarthritic changes have developed, realistically therapy is likely only to be palliative. Intraarticular medication with small doses of corticosteroids, such as 10 mg of

triamcinolone acetonide combined with hyaluronan, may give temporary relief. A controlled exercise regimen may help, and an arthroscopic debridement prolongs working life in some horses.

Prognosis

The femoropatellar joint is more forgiving than the femorotibial joints, and although OA will not resolve, if mild it may be tolerated enough for a horse to perform useful work. More severely affected horses are unlikely to return to athletic use.

Distal Luxation of the Patella

One report of distal luxation of the patella has been made.⁵⁵ The horse held the affected limb flexed and non-weight bearing. The patella was relocated with the horse under general anesthesia, and when the horse was reexamined 3 months later, no lameness was seen.

Patellar Ligament Injuries

Patellar ligament injuries are rare. Sprain of the middle patellar ligament is the most common, although lateral patellar ligament injuries also occur.⁴⁹ There may be an association between middle patellar desmitis and previous medial patellar desmotomy. Jumping horses are most commonly affected. Lesions may occur unilaterally, or less commonly bilaterally.

Signs and Diagnosis

Lameness can be moderate to severe in the acute phase but varies. The severity of lameness is usually commensurate with the degree of ligamentous damage and is most severe in horses with partial ruptures. Sometimes no localizing signs are apparent, but femoropatellar effusion, periarticular thickening, or edema may be seen in some horses. Intraarticular analgesia of the femoropatellar joint may slightly improve lameness in some horses, but in others there is no effect on the lameness. The diagnosis is confirmed by ultrasonography. Proximal, midbody, and distal lesions have been identified. Differentiation should be made between core lesions and partial-thickness tears. Radiological changes are unusual, and one should bear in mind that enthesal change on the cranial distal aspect of the patella may be seen as an incidental radiological finding. However, extensive enthesal new bone may be of clinical significance. Scintigraphy may show focal IRU in the patella or more commonly the cranioproximal aspect of the tibia in association with proximal or distal lesions of the middle patellar ligament.

Treatment

Horses with severe injuries may require rest for up to 6 months. In one Editor's experience (SJD) conservative management has yielded poor results in horses with extensive core lesions, and treatment by injection of porcine urinary bladder matrix or mesenchymal stem cells has improved the prognosis. The presence of periligamentous fibrosis is a poor prognostic finding. Horses with partial-thickness tears have also responded poorly to any form of management, including surgical debridement.

Prognosis

Lameness is often slow to resolve and is recurrent in some horses.

Femorotibial Joint

Subchondral Cystic Lesions

The cause of subchondral bone cysts and other osseous cystlike lesions is still unknown. The distal weight-bearing aspect of the medial femoral condyle is the most frequent site for subchondral bone cysts.⁵⁶ Osseous cystlike lesions were identified in the caudal aspect of the femoral condyles in foals.⁵⁷ Osseous cystlike lesions also occur in the proximal aspect of the tibia. Lesions thought to result from osteochondrosis were in the lateral aspect of the tibia, and those associated with OA were more common medially in a report of 12 horses.⁵⁸ Subchondral bone cysts and osseous cystlike lesions may be a form of osteochondrosis,⁵⁹ but trauma is also probably an important factor. Subchondral bone cysts in the medial femoral condyle have been produced experimentally after development of full-thickness defects in cartilage and subchondral bone.²⁴ Lesions did not form if the defects were made only in cartilage. The lining of these lesions has been shown to contain active inflammatory enzymes that cause bone resorption.⁶⁰ In the literature the syndrome in the young horse is emphasized, but in my experience subchondral bone cysts and osseous cystlike lesions occur in any age group, mostly apparent as a primary lesion but sometimes as a sequel to OA.

Signs and Diagnosis

The condition is reported to be more common in horses less than 4 years old,⁵⁶ but in my practice it is encountered in horses of all ages.⁵ Lameness is mild to moderate but can be severe at first and acute in onset. Lameness may be intermittent, especially in older horses. Affected horses seem to be lamer when turning. Occasionally mild medial femorotibial effusion occurs, but often no signs are obvious on physical examination. Intraarticular analgesia of the medial femorotibial joint may be required to diagnose the site of pain causing lameness. Because the subchondral bone is probably the site of pain, local anesthetic solution must diffuse into the lesion and may not be completely effective. A 50% improvement in lameness justifies radiographic examination.

The caudocranial, caudolateral-craniomedial oblique, and flexed lateromedial radiographic images are the most useful for demonstrating the lesion. Subchondral bone cysts in the medial femoral condyle are relatively round or oval, with a variably sized base and communication with the joint (Figure 46-5). Increased radiopacity of the rim is usually seen only in horses with older lesions. Radiological signs of OA may also be apparent in some horses. The osseous cystlike lesions in the tibia have a similar morphology. Subchondral bone cysts can also occur as incidental radiological findings in sound horses. Lesions in the caudal aspect of the femoral condyles in foals may appear radiologically as localized or extensive osseous defects. Scintigraphic findings in horses with subchondral bone cysts are inconsistent,²⁴ but most have IRU. Flattening or indentation of the distal medial femoral condyle is sometimes seen radiologically and may be a precursor of a subchondral bone cyst. These lesions are relatively common and frequently do not cause lameness. Occasionally IRU is seen associated with these defects.⁵ In my experience, positive scintigraphic findings, together with a positive response to diagnostic analgesia, are good indications that

Fig. 46-5 • A caudocranial radiographic image of the right stifle of a yearling Thoroughbred colt. Medial is to the left. There is a subchondral bone cyst in the medial femoral condyle with increased radiopacity of the rim and a wide base that communicates with the medial femorotibial joint.

the defect is a cause of lameness, but some scintigraphically positive lesions do not result in clinical signs; the Editors consider this unusual. Arthroscopic evaluation of horses with subtle osteochondral defects of the medial femoral condyle detected radiologically revealed that flattening of the medial condyle or a subchondral lucent area was associated with a focal or more generalized cartilage defect in 18 of 20 and four of four limbs, respectively. Treatment by abrasion arthroplasty and microfracture resulted in seven of nine horses with focal cartilage lesions returning to full athletic function, and two of six with generalized cartilage pathology.⁶¹

Treatment

Conservative treatment involves stable or pasture rest, with or without nonsteroidal antiinflammatory medication or intraarticular corticosteroids.^{62,63} Horses with nonarticular osseous cystlike lesions or small articular defects are probably best managed conservatively. For articular lesions and horses that do not respond to conservative management, arthroscopic debridement has been advocated.^{56,59,64} Debridement of the cyst lining and removal of all debris from the joint are the goals. Experimentally the use of cancellous bone grafts did not improve the outcome.⁶⁵ Postoperative intralesional corticosteroid has been advocated to suppress the inflammatory mediators.⁶⁰ Subchondral bone forage is contraindicated because reports indicate that it may worsen the lesion.⁵⁶ Debridement of small medial condylar defects should be approached with caution because this may provoke a worsening of the lesion. Tibial osseous cystlike lesions can be debrided arthroscopically, but many of them lie beneath the cranial meniscal ligament, which must be divided to gain access. It was reported that the success rate for horses more than 3 years of age was poor (35% of 46 horses sound at follow-up

evaluation),⁶⁶ and many surgeons now lean toward intralesional corticosteroid treatment. There is evidence that numerous injections of corticosteroids into the fibrous lining of the cyst under arthroscopic guidance is the most effective method of management in older horses, and early reported success appears to be superior to that achieved using debridement in older horses (13/18 horses sound at follow-up evaluation).⁶⁷

Prognosis

A 50% success rate was reported with conservative treatment of horses with medial femoral condylar subchondral cysts, but remodeling of bone may be more prolonged than with surgical treatment.⁶² Arthroscopic debridement carries a 70% to 75% success rate in horses less than 3 years old.^{56,64} Preexisting OA results in a more guarded prognosis. Improvement of clinical signs after surgery frequently occurs without radiological resolution. Limited reports of surgical treatment of tibial osseous cystlike lesions⁵⁸ suggest that horses with lateral proximal tibial osteochondrosis-associated lesions may respond best, and this is also my experience.

Meniscal and Meniscal Ligament Injuries

The cause of meniscal injuries in horses is not well documented, but in dogs meniscal injuries are considered to be caused by crushing forces combined with tibial rotation and flexion or extension of the stifle.⁷ Meniscal injuries have also been reported in horses.⁶⁸⁻⁷¹ I have diagnosed 126 meniscal injuries arthroscopically as the primary cause of lameness. The medial meniscus was affected in 80% of horses. The cranial ligaments of the menisci were involved in nearly all horses.⁷² Concurrent injury to other structures in the stifle was frequently diagnosed, including articular cartilage damage on the femoral condyles in 96 horses and cruciate injury in 18 horses. Secondary medial collateral ligament injury was not diagnosed. Primary medial collateral ligament rupture with secondary meniscal injury was not included in the series. Twenty-seven of 79 other horses that were examined arthroscopically and that had other stifle injuries, but no evidence of meniscal damage, did have fibrillation of the axial borders of the cranial ligaments of the menisci.⁶⁸ The clinical significance of this is uncertain.

Signs and Diagnosis

Lameness is often acute and severe in onset after trauma but mostly becomes low grade and persistent. Distention of the femoropatellar or medial femorotibial joints can be expected in horses with more severe injury.⁷¹ Lameness is exacerbated by flexion of the limb in about 90% of horses.⁵⁵ Diagnostic analgesia is usually necessary to confirm the site of pain causing lameness but may not render the horse completely sound. Radiological signs occurred in 52% of horses that I have diagnosed with meniscal injury. New bone formation on the cranial aspect of the medial intercondylar eminence of the tibia was the most frequent finding (25%)⁷² and appears to be more common with meniscal than cruciate ligament disease, in which it occurred in five of 71 (7%) cases treated at my hospital⁷² (Figure 46-6). Dystrophic mineralization and osteoarthritic radiological changes may be seen in horses with severe lesions. Ultrasonography can be a valuable aid in diagnosis, although some lesions will not be visible

Fig. 46-6 • Lateromedial radiographic image of the left stifle of a 7-year-old Thoroughbred cross gelding. There is new bone on the cranial aspect of the intercondylar eminences of the tibia (arrow). Note also the large radiolucent zone in the proximal aspect of the tibia. There is an old osteochondrosis lesion involving the lateral trochlear ridge of the femur. Arthroscopic examination revealed a tear of the medial meniscus.

Fig. 46-7 • Arthroscopic photograph of the left lateral femorotibial joint of a 6-year-old eventer gelding. The lateral meniscus has a grade 2 tear (arrow).

ultrasonographically, and artifactual changes can be difficult to differentiate.^{73,74}

Arthroscopy offers the best chance of a definitive diagnosis and an assessment of concurrent damage. Because only the cranial and caudal poles of the menisci can be seen, assessment of meniscal injury is limited. Owing to these limitations, I graded changes visible from cranially as follows:

1. Tears extending longitudinally from the cranial ligament into the meniscus, with minimal separation
2. Tears involving the cranial pole in which the extent of the injury is visible (Figure 46-7)

3. Severe tears that extend beneath the femoral condyle and that cannot be completely assessed or debrided⁷¹

Treatment

Horses with acute stifle injuries that have no definitive diagnosis should be managed with rest and antiinflammatory medication, followed by controlled exercise. Arthroscopy is indicated if conservative therapy is unsuccessful or for severely lame horses. Grade 1 meniscal tears can only be superficially debrided. Intraarticular suturing for some horses may be a way forward. Grade 2 and 3 tears are debrided as effectively as possible by removing all loose tissue. A careful assessment of visible concurrent damage should be made. Postoperatively controlled exercise begins at 2 to 3 weeks and can gradually be increased over 3 months, depending on progress and the extent of the injury. Free exercise at pasture should be avoided for 6 months.

Prognosis

Return to full athletic use can be expected in about 50% of horses overall, although improvement may be seen in another 10%.^{71,72} Full function was regained in 60% of 67 horses with grade 1 tears, 65% of 35 horses with grade 2 tears, 10% of 24 horses with grade 3 tears, and neither of 2 horses with two menisci affected. In the Editors' experience the prognosis for return to full athletic function in upper level sports horses is guarded. Concurrent articular cartilage damage significantly worsened the prognosis,⁷¹ and nine of 18 horses with concurrent cruciate ligament injury became sound. Horses treated arthroscopically within 2 months of injury fared 25% better than those treated later than 2 months.⁷² If radiological signs of OA were present, the prognosis was also significantly worsened.⁷¹

Cranial and Caudal Cruciate Ligament Injuries

In the dog the cranial cruciate ligament can be injured when the stifle is in hyperextension or after sudden rotation with the stifle in flexion,⁷ and this is likely to pertain to the horse. Direct trauma to the joint or degenerative change in the ligament can also lead to cruciate injury in the horse.^{5,75} Experimentally⁷⁶ and in my clinical experience⁵ the cranial cruciate ligament fails most frequently at midbody level, but avulsions of its tibial and less often of its femoral attachments have been reported.^{75,77} Caudal cruciate ligament injuries occur less frequently.⁷⁸ Concurrent injuries, including damage to the medial collateral ligament, the menisci, and articular cartilage, are often associated with cruciate tears.^{75,79}

Signs and Diagnosis

Lameness is often associated with a history of trauma and is usually acute in onset and severe at first. Distention of the femoropatellar or the femorotibial joints is sometimes present. In horses with severe injuries, crepitus may be detectable. The cruciate draw test appears to be valueless in the conscious horse, but a proximal limb flexion test is usually positive, especially with severe injury. In horses with mild injuries, diagnostic analgesia is required to confirm the site of pain causing lameness. In my series of 75 horses with cranial and caudal cruciate ligament injuries diagnosed at arthroscopy, radiological signs included the following⁵:

Fig. 46-8 • An arthroscopic view of the right femorotibial joint of an 8-year-old Warmblood gelding. The median septum has been removed with the motorized synovial resector to reveal a chronic, low-grade fiber disruption of the cranial cruciate ligament.

- No changes in at least 56% of horses.
- Fracture of the intercondylar eminence of the tibia; however, this can occur without clinically significant cruciate injury.
- New bone formation cranial to the intercondylar eminence of the tibia. This finding was three times more common in horses with meniscal injuries than those with cruciate ligament injuries in my series.
- Bony resorption or fragmentation at the femoral attachment of the cruciate ligaments.
- Cranial displacement of the tibia with cranial cruciate ligament rupture.
- OA, or mineralization of the ligament, associated with chronic lesions.

Ultrasonographic evaluation of the cruciate ligaments is difficult. Arthroscopy offers the best evaluation of the cruciate ligaments. The cranial cruciate ligament is covered by the median septum, which may make the ligament difficult to assess, but the septum is often disrupted in cranial cruciate ligament injury. Motorized debridement of the septum may be required to see the ligament. The caudal cruciate ligament is viewed from the cranial and caudal aspects of the medial femorotibial joint. The caudal medial aspect of the femorotibial joint can be approached cranially⁸⁰ or caudally.⁸¹ Mild cranial cruciate ligament changes are difficult to quantify because of inflammatory changes in the median septum, but fiber disruption is seen in moderate injuries (Figure 46-8). With acute, severe injuries of the cranial cruciate ligament, inflammatory debris must be removed before the torn ends of the ligament can be seen. Concurrent articular cartilage or meniscal damage within the joint is common.

Treatment

With acute injuries the same treatment criteria apply as for meniscal injuries. The indications for arthroscopy and postoperative management are also similar. Arthroscopic debridement is best performed with a motorized synovial

resector. Repair in horses with complete cruciate ligament rupture has not been reported, and the best treatment that can be offered is good debridement of loose tissue to allow less severe injuries the best chance to heal.

Prognosis

Prognosis is poor in horses with moderate to severe injuries. In one report, two of 10 horses were pasture sound and one raced,⁷⁵ and in another report two of six were pasture sound.⁷⁹ In my series, lameness persisted in four of six horses with severe injuries; 10 of 17 horses with moderate injuries became sound; and 18 of 29 horses with minor superficial changes became sound.⁵

Collateral Ligament Injuries

Injury of the medial collateral ligament is more frequently diagnosed than injury of the lateral collateral ligament. Such injury is associated with acute trauma, which, as in the dog, probably involves a medial or lateral force on the joint or distal aspect of the limb.⁷⁹ Concurrent injury of the menisci or cruciate ligaments commonly occurs in horses with severe injuries,^{79,82} but not necessarily in those with more moderate injuries.

Signs and Diagnosis

The most easily diagnosed collateral ligament injuries are complete ruptures of the medial collateral ligament, which manifest as acute, severe lameness after trauma. Instability of the stifle occurs with swelling and pain over the ligament. Sprains of the collateral ligaments are less obvious. Heat and pain may be palpable, and chronic thickening develops in some horses. The collateral ligament test can be useful but is not specific. Flexion of the limb is usually painful, but intraarticular analgesia of the medial femorotibial joint may be negative. If complete rupture of the ligament has occurred, stressed caudocranial radiographs are diagnostic. Widening of the joint space occurs on the affected side (Figure 46-9). Enthesophyte formation at the origin and insertion may be seen in horses with chronic injuries. Ultrasonography can be helpful in diagnosing and assessing the injury.¹⁸

Treatment

Horses with mild sprains, in which no instability occurs, are treated with stall rest for 6 weeks and antiinflammatory medication until the inflammation subsides, followed by controlled exercise for another 6 weeks. One report describes the repair of a complete rupture of the medial collateral ligament using braided polyester material attached to two 6.5-mm cancellous screws in the femur and tibia to stabilize the joint.⁸³ Orthopedic wire was originally used, but it dislodged postoperatively. The surgery is a salvage procedure and is not well documented, and concurrent injury and horse compliance should be carefully assessed before undertaking surgery.

Prognosis

Horses with mild sprains have a moderate chance of returning to athletic use, depending on the extent of any concurrent injury. Results are not well documented, and in my view the prognosis is probably poor if entheseous change develops at the medial collateral ligament attachments. The prognosis for horses with complete ruptures is grave.

Fig. 46-9 • Stressed caudocranial radiographic image of the left stifle of a 10-year-old riding horse with rupture of the medial collateral ligament of the femorotibial joint. Medial is to the right. There is widening of the medial joint space. Note also the osseous opacity proximal to the intercondylar eminences (arrows).

The horse described above that was treated surgically was comfortable at pasture until it became lame after falling 9 months postoperatively. Because associated meniscal or cruciate injury is common, a high chance exists of OA in the long term, even if the medial collateral ligament heals.

Articular Cartilage Trauma

Articular cartilage defects on the medial or lateral femoral condyles or on the axial part of the tibial plateau are frequently encountered during arthroscopic examination. Usually they accompany other femorotibial injuries, but occasionally they are the only finding, in which case they may be considered the primary cause of lameness.⁸⁴ Cartilage lesions were diagnosed as the primary cause of lameness in 150 of 632 horses undergoing diagnostic arthroscopy of the stifle in my series.⁵ Primary lesions may be seen on both the medial and lateral femoral condyles.

Signs and Diagnosis

Horses in which articular cartilage lesions are a primary cause of lameness usually have mild to moderate lameness. Diagnostic analgesia is required to define the site of pain causing lameness. Abnormalities are rarely seen radiologically. At arthroscopy, a variety of lesions may be present. These include thickening, softening, and creasing of the cartilage, widespread fibrillation, focal tufts of fibrillated cartilage, circumscribed nodules of cartilage, apparent tears of the articular surface, and areas of exposed subchondral bone.^{72,84,85}

Treatment

Doubt about the long-term effect of debridement of cartilage lesions still exists.⁸⁶ Small, full-thickness lesions are probably best debrided to subchondral bone; micro-picking the bone appears to improve healing to a degree.⁸⁷ The effect of smoothing partial-thickness defects is still controversial and may provoke the development of an

osseous cystlike lesion.^{56,86} Debris should be thoroughly lavaged from the joint. Postoperative intraarticular medication with disease-modifying OA drugs could be helpful.

Prognosis

The prognosis for return to soundness for horses with cartilage defects is generally considered guarded. Six of seven horses with focal defects returned to racing, but five horses with larger lesions remained lame.⁸⁴ In my practice, a full-thickness articular cartilage defect was diagnosed arthroscopically in 38 horses as being the primary cause of lameness. Sixteen of 24 horses (67%) for which follow-up information was available became sound.⁵ Of the horses with less severe lesions, 30 of 38 (79%) of those with mild changes (mild fibrillation, mild soft creased cartilage, mild focal fibrillation, $n = 77$) and 17 of 22 (77%) of those with moderate changes (generalized fibrillation, shear lesions, severe thickening and creasing, partial-thickness linear defect, $n = 37$) returned to full use. In the Editors' experience prognosis for upper level sports horses to return to full athletic function is guarded.

Osteoarthritis

OA of the femorotibial joint can be a sequel to any injury described in this chapter that has the potential to damage the articular cartilage. OA is likely to develop when the initial tissue damage is severe, is not treated, or is treated ineffectively. OA of the medial femorotibial joint is much more common than in the lateral femorotibial joint.

Signs and Diagnosis

Many horses have a history of lameness that has already been treated or chronic lameness of varying intensity. Diagnostic analgesia may be required to identify the site of pain causing lameness, but joint effusion and thickening are palpable on the medial aspect of the joint in many horses. Flexion of the limb is painful, and some horses resent holding up the limb for shoeing. Radiological examination reveals typical changes associated with OA, including osteophytosis, flattening of the articular surfaces of the femoral condyles, increased radiopacity and radiolucent zones in the subchondral bone, narrowing of the joint space, and dystrophic mineralization of soft tissues.

Treatment

Management of OA is at best palliative. If possible, the inciting lesion should be treated appropriately in an attempt to prevent worsening of the changes. Intraarticular corticosteroids, glycosaminoglycans, or any medication designed to slow the progress of the disease, as well as arthroscopy in some horses, may give temporary relief.

Prognosis

Once radiological changes of OA are manifest, in particular, joint space narrowing, the prognosis for athletic soundness is poor. With careful management, less severely affected horses may be able to perform light work or be kept at pasture.

Subchondral Bone Trauma and "Bone Bruising"

Early experience with CT¹⁷ and MRI is providing some explanation for horses with lameness that is improved by intraarticular analgesia of the stifle joints, but in which

radiography, ultrasonography, scintigraphy, and, in some horses, exploratory arthroscopy fail to explain the cause of pain. Primary osseous lesions have been identified reflecting bone trauma.

Fractures Involving the Stifle

Fractures of the Patella

External trauma is the commonest cause of patellar fracture in the horse.⁸⁸ Contraction of the quadriceps muscles may be the cause of some avulsion fractures. The majority of horses have a history of direct trauma, such as a kick, or an impact on the stifle by hitting a fixed fence while jumping. If the trauma occurs while the stifle is in flexion, the patella is fixed against the trochlear ridge of the femur, which is thought to render it more vulnerable to fracture.⁸⁹

A variety of fracture morphology is seen.^{89,90} Sagittal fractures of the medial aspect of the patella are probably the most frequent. These are usually articular, and the fragment often involves a substantial area of the attachment of the parapatellar fibrocartilage of the medial patellar ligament. Fragmentation of the base of the patella sometimes accompanies these fractures⁸⁸ or may be seen separately. Nonarticular fractures are mostly seen as mildly displaced fragments on the cranial aspect. Complete horizontal fractures are severe injuries, and the massive forces exerted by the extensor muscles have an important bearing on their management. Complete sagittal fractures are less catastrophic because the distracting forces are not as strong. Comminuted fractures of the whole body of the patella occasionally occur after severe trauma.

Signs and Diagnosis

The history and clinical signs often strongly suggest the possibility of patellar fracture. Initially lameness may be severe and remains so in horses with midsagittal and horizontal fractures. In horses with many of the smaller avulsion fractures or fractures of the medial aspect, lameness becomes moderate to mild after a few days. Often evidence of trauma and local swelling are apparent in the stifle region. Crepitus is occasionally present, and pain may be elicited on palpation of the patella. The femoropatellar joint is usually distended. Horses with chronic, less severe fractures often have surprisingly little direct evidence of the injury. Flexion of the limb is usually painful.

Radiography is essential to confirm the diagnosis and to evaluate the fracture. Lateromedial images may give no indication of the fracture, so a cranioproximal-craniodistal image is essential (Figure 46-10). Severely injured horses greatly resent positioning for this radiographic image and may require analgesia. Occasionally general anesthesia is required, but it should not be attempted without treatment options being in place.

Treatment

Horses with open wounds must be treated with debridement and antibiotics, and it is vital to establish if joint infection exists and treat it appropriately. Horses with small nondisplaced, nonarticular fractures may be managed conservatively with stable rest. Most heal by fibrous union only. Horses may return to work in 8 weeks. Horses with fragments originating from the base of the patella need arthroscopic debridement if debris is loose in the joint.

Fig. 46-10 • Cranioproximal-craniodistal radiographic image of the right patella of a 10-year-old eventer gelding that hit a cross-country fence with the right stifle. Medial is to the right, and cranial is to the top. There is a displaced fracture of the medial pole of the patella.

Fig. 46-11 • Arthroscopic photograph of the left patella of the horse in Figure 46-10 showing the fracture line (with probe inserted) in the medial aspect of the patella.

Small fragments at the base of the patella, which are embedded in the soft tissue attachments, may not require removal.⁹¹ Articular fractures of the medial aspect are best removed.⁸⁸ This can be done by arthrotomy or arthroscopy (Figure 46-11) and requires careful dissection of the fragment from the medial patellar ligament. The distal end of the fracture is clearly seen arthroscopically. Concurrent joint damage should be evaluated and can have an important bearing on the outcome. Horses with complete horizontal fractures must be treated by internal fixation.^{89,92,93}

Lag screw fixation with 5.5-mm cortex screws or partially threaded 6-mm cancellous screws, possibly with reinforcement with tension band wiring, is necessary to combat the huge distraction forces of the extensor muscles. Recovery from general anesthesia has to be carefully controlled by delaying attempts of the horse to stand by use of sedation to avoid breakdown of the repair. Sagittal fractures can also be repaired using the lag screw principle.⁹⁴

Prognosis

Horses with small, nonarticular fractures usually have a good prognosis with conservative management.⁹¹ Ten of 12 horses with medial fractures without concurrent joint disease treated by partial patellectomy returned to athletic use.⁸⁸ My experience has been similar. Internal fixation of horizontal and midbody vertical fractures can be rewarding, but the risk of breakdown during recovery from general anesthesia is substantial, especially in horses with horizontal fractures. Horses with severely comminuted fractures have a poor prognosis.

Fracture of the Intercondylar Eminence of the Tibia

These fractures have been described as avulsion fractures of the insertion of the cranial cruciate ligament.^{75,95,96} However, because the insertion of the cranial cruciate ligament is cranial to the eminence, they are not avulsions but are likely caused by trauma from a lateral force from the medial femoral condyle on the intercondylar eminence.⁹⁷

Signs and Diagnosis

The history and clinical signs are similar to those seen with other acute, severe stifle injuries, and confirmation of the fracture is made radiologically. The caudocranial and flexed lateromedial images are the most useful. Once the acute inflammation has subsided, lameness can be mild to moderate in horses that do not have clinically significant injuries to vital soft tissue structures.

Treatment

An arthroscopic assessment is essential for evaluating the fracture and concurrent soft tissue damage in the joint, which is extensive in some horses. If accompanying soft tissue injuries are not severe, treatment can be rewarding. Small fragments should be removed. Horses with large fragments can be treated by internal fixation.⁹⁷ Alternatively, large fragments can be removed, but this depends on fragment configuration and the involvement of soft tissue structures, such as the cranial cruciate ligament or the cranial ligament of the medial meniscus that wraps around the cranial surface of the eminence.^{95,96}

Prognosis

If soft tissue damage is reparable, the prognosis for fracture treatment can be good. The possibility always exists of articular cartilage or soft tissue damage that is not detected at arthroscopic examination⁷⁸ but that may ultimately cause chronic lameness.

Fracture Fragments Originating from the Femoral Trochlear Ridges or Femoral Condyles in Adult Horses

Fractures of the distal aspect of the femur usually result from direct external trauma, such as hitting a fence while jumping, a penetrating wound, or a kick.^{91,98}

Signs and Diagnosis

Characteristically there is a sudden-onset, moderate to severe lameness, with a history of acute trauma. Effusion of the femoropatellar joint is usually present. With condylar fractures there is also effusion of the medial femorotibial joint. Crepitus may be present, and flexion of the joint causes pain. In the femoropatellar joint, fragments arise most commonly from the distal aspect of the lateral

trochlear ridge and are best seen on flexed and standing lateromedial radiographic images. Caudocranial images are also important for identifying the position of fragments in the cranial or caudal femorotibial joints, and cranioproximal-craniodistal oblique images are necessary to rule out concurrent patellar fractures. The fracture site may not be obvious. Because these fractures are commonly caused by direct trauma, often the stifle region has a wound, and in these circumstances a strong chance of infection in the joint exists. Infection should be ruled out by arthrocentesis. Infection can also occur by extension into the joint, hours or even days after the injury. If a sudden increase in lameness occurs, arthrocentesis must be repeated.

Treatment

Fragments should be removed to prevent the development of OA. Most can be removed arthroscopically,^{91,98} but arthrotomy may be necessary for excision of large fragments.⁹⁹ In many horses I prefer to wait a few days before examining the joints arthroscopically because the initial intraarticular hemorrhage hinders surgery. Many horses have a severely inflamed synovium in which fragments may be embedded and difficult to find. Fragments in the femoropatellar joints are often loose, whereas in the femorotibial joints they more often have soft tissue attachments, but conditions vary greatly, and intraoperative radiography to ensure removal of all fragments can be useful. Evaluation of the remainder of the stifle joint for concurrent injuries is important.

Prognosis

Horses with trochlear ridge fractures have a good prognosis after fragment removal.^{91,98} If no clinically significant soft tissue damage occurred, the prognosis is also favorable after removal of fracture fragments in the femorotibial joint. One should bear in mind on the initial assessment that some of these injuries are not as catastrophic as the radiological changes suggest.

Salter-Harris Fractures of the Femur, Types III and IV

Type III and IV Salter-Harris fractures of the femur tend to occur in older foals and usually result from a fall with the limb in adduction or from an external trauma. From limited reports, type II fractures, which are not discussed in this section, are the most common physeal fracture; however, of the articular fractures, type IV fractures appear to be more common.¹⁰⁰⁻¹⁰² Type IV fractures often have a characteristic configuration in which the fracture begins in the trochlear ridges in the horizontal plane and exits through the caudal lateral diaphyseal cortex.¹⁰⁰

Signs and Diagnosis

Foals with minimally displaced fractures may be weight bearing, but the others usually have acute, severe lameness, swelling, pain, and often crepitus in the affected joint. Radiology confirms the fracture and should include enough views to establish its configuration.

Treatment

Conservative treatment may be appropriate for horses with stable, minimally displaced fractures.¹⁰⁰ Internal fixation is indicated for horses with displaced or unstable fractures. Repairs using lag screw fixation, cobra head bone plates,

and angle blade plates have been reported.¹⁰⁰⁻¹⁰³ Implanting screws through the articular cartilage of the femoral trochlea is sometimes necessary, and crossing the physis with an implant does not seem to have affected growth in the distal femoral physis in older foals.¹⁰⁰ The dynamic condylar screw plate may be of value.

Prognosis

The few published reports¹⁰⁰ indicate that foals with minimally displaced fractures have a good chance of achieving athletic use with conservative treatment. If surgery is required, the outcome is more equivocal, but good success has been achieved in some horses.

Fractures of the Tibial Tuberosity

The tibial tuberosity is a relatively exposed structure and is susceptible to fracture after direct trauma, such as a kick, or a collision with a fence. These fractures are not associated with the physis of the tibial tuberosity and may not be authentic avulsion fractures, although the lateral patellar ligament is often involved. If patellar ligaments are involved, fractures may displace proximally.¹⁰⁴ If proximal displacement is observed radiologically, a tension band technique should be used for surgical repair, although conservative management can be successful (see below). Traction apophysitis similar to Osgood-Schlatter disease in people has been reported in horses¹⁰⁵ but is rare. In the horse reported, lameness was mild, and small fragments detached from the cranial aspect of the tibial tuberosity were visible radiologically. A variety of fracture configurations occur, from small fragments on the cranial proximal aspect to large fractures extending from distal to the tibial crest to proximally into the femorotibial joint.

Signs and Diagnosis

Most horses are acutely, severely lame immediately after sustaining the fracture, but in some this may settle into a milder lameness if left untreated. Swelling and crepitus are common. Occasionally with minimally displaced fractures there is only mild lameness and no history suggestive of a fracture. A wound on the lateral aspect of the tibia may be present, and intraarticular fractures may be associated with joint effusion. Care should be taken to rule out other injuries in the stifle, such as fracture of the patella, or joint infection if an open wound exists. Infection can even develop by extension into the joint through a skin graze. Because of the lateral curvature of the tibial tuberosity, several radiographic images are often required to identify the contour of the fracture, the caudolateral-cranio-medial oblique image being the most useful. The tibial tuberosity does not fuse until at least 3 years of age,¹⁰⁶ and its physis should not be confused with a fracture.

Treatment

Nonarticular fractures may heal with conservative treatment. Horses with large intraarticular fractures can also be treated by internal fixation. Lag screw fixation does not provide a secure enough repair, so tension band wiring,¹⁰⁷ a lateral narrow dynamic compression plate,¹⁰⁸ and a cranial narrow dynamic compression plate⁸⁵ have been used. I believe that the most secure repair is achieved with the latter (Figure 46-12). The plate should extend well distal to the distal extremity of the fracture to withstand

Fig. 46-12 • Postoperative lateromedial radiographic image of the right tibia of a 13-year-old pony gelding that had sustained a fracture of the tibial tuberosity. The horse has been managed using internal fixation with a narrow dynamic compression plate.

the distraction forces of the quadriceps muscles. Because of the shape of the cranial proximal aspect of the tibia, contouring of the plate demands considerable twisting and bending, but this does not seem to affect its efficacy. A technique for preoperative plate bending was reported as a way of saving surgery time,¹⁰⁹ but in my experience plate contouring is not especially time consuming. Most horses are substantially more comfortable postoperatively, but they should be prevented from lying down for 2 weeks.

Prognosis

Conservative treatment of horses with nondisplaced, small fragments results in a good prognosis. Horses with larger fractures may also respond to conservative treatment with complete return to soundness. Fifteen horses with nonarticular fractures were treated conservatively, and 12 returned to full use. Neither size nor displacement of the fragment affected outcome, and the horses returned to work in a mean of 6.3 months.¹¹⁰ Those that remained lame had concurrent soft tissue injury in the stifle.¹¹⁰ Good results for return to full athletic function have been reported after repair with a cranially applied plate,¹⁰⁴ and in my view this is the treatment of choice for articular fractures. A potential risk exists for failure of the repair during recovery from general anesthesia or the early postoperative period¹⁰⁸ or for catastrophic tibial fracture. This emphasizes the importance of adequate fixation and restriction of the horse during early convalescence.

Fractures of the Fibula

Fracture of the fibula is usually caused by direct trauma and is a rare injury (see Chapter 45). Lameness is often moderate to severe at first. Palpation of the region may not elicit obvious pain, but radiography should be diagnostic. The

caudocranial image is the most useful, but great care must be taken to differentiate a fracture from persistent radiolucent lines that result from separate ossification centers in the fibula. As many as three of these lines can be present, and they may be irregular. Scintigraphy is a useful aid to diagnosis in the absence of localizing clinical signs or if one has difficulty in radiological interpretation. From limited experience, confinement of the horse for 2 to 4 months is usually long enough for reasonable healing to take place, and the prognosis is good.

Other Diseases

Avulsion of the Origin of the Fibularis (Peroneus) Tertius and Long Digital Extensor Tendon

Avulsion of the origin of the fibularis tertius and long digital extensor tendon is a relatively rare condition in horses and is usually caused by sudden, forceful hyperextension of the hindlimb. Midsubstance tears are probably more common than avulsions of the common tendon of origin of the fibularis tertius and long digital extensor muscles, but the latter have been reported in foals.¹¹¹⁻¹¹³ Avulsions of the origin of the fibularis tertius and long digital extensor muscle occasionally occur in adult horses,⁵ although more distal injuries are commoner. Foals may be more likely to suffer avulsions because of weaker bone.¹¹² Minor disruption of the common tendon of origin may be seen arthroscopically.⁵

Signs and Diagnosis

The classical sign of rupture of fibularis tertius and avulsion of its origin is the ability to extend the hock while the stifle is flexed, resulting in a dimpling of the common calcaneal ("Achilles") tendon. Synchronous flexion of the hock and stifle was reported with avulsions of the origin, presumably because the avulsed bone is held by the joint capsule.¹¹² Horses may bear weight normally, but during the protraction phase of a stride, the distal limb appears flaccid. Lameness can be severe at first, and distention of the femorotibial and femoropatellar joints may be present. Radiological examination is necessary for diagnosing avulsion fractures. Minor disruptions of the tendon of origin manifest as nonspecific lameness associated with pain in the stifle and can be diagnosed by arthroscopic examination; they may accompany other stifle injuries.⁵

Treatment

Horses with injuries to the tendon of origin are usually best evaluated arthroscopically, which also offers the opportunity to check for concurrent injury. Small bone fragments can be removed, but large fragments embedded in the joint capsule may be better left.¹¹² Six weeks of stable rest followed by controlled exercise for 3 months is recommended after surgery.

Prognosis

Horses with avulsion injuries have a guarded prognosis for full soundness, but successful outcome has been reported.¹¹² Minor disruptions of the origin may heal but much depends on concurrent injuries.

Calcinosis Circumscripta

Calcinosis circumscripta lesions are described as calcified, granular, amorphous deposits that induce fibrous

reaction.¹¹⁴ They usually lie in the subcutaneous tissue close to joints or tendon sheaths. The lateral aspect of the stifle adjacent to the fibula is the predilection site for these lesions,¹¹⁴⁻¹¹⁶ but they have been reported on the dorsolateral surface of the hock,¹¹⁴ the neck, and the shoulder.^{114,115} Calcinosis circumscripta is an uncommon condition, more often seen in young horses. The cause is unknown.

Signs and Diagnosis

The usual reason for examination is an unsightly lesion that has been slowly increasing in size. Occasionally the lesion appears to affect the horse's gait. Lesions are usually hard, well circumscribed, and firmly attached to underlying tissue. The overlying skin is not involved. Caudocranial radiographs show a circumscribed, roughly oval lesion of mineralized tissue (Figure 46-13) lying close to the lateral aspect of the femorotibial joint, with the bulk of the lesion distal to this. These lesions may be seen incidentally on scintigraphic examination as focal areas of intense IRU on the lateral proximal aspect of the crus. The lesion is clearly visible in a caudal image in a subcutaneous location, superficial to the tibial cortex, but in a lateral image IRU could be confused with a proximal tibial stress fracture.

Treatment

Treatment is only indicated if the lesion causes clinical complications or for cosmetic reasons. Surgical excision is necessary to remove the mass. Care should be taken when embarking on excision because some lesions are attached to the femorotibial joint capsule, which may be entered inadvertently. Steps should be taken to prevent postoperative seroma formation by closing dead space, suturing a stent bandage over the wound, and preventing the horse from lying down for several days postoperatively. The mass usually has a thick fibrous capsule and contains deposits of gritty material.

Fig. 46-13 • Caudocranial radiographic image (lateral is to the left) of the left stifle of an 8-year-old riding horse with an oval mass of mineralized tissue lateral to the head of the left tibia. The lesion is typical of calcinosis circumscripta.

Prognosis

In horses that are not treated, the mass remains but may not cause complications. A good result can be expected after surgical excision. Regrowth has not been reported, but postoperative problems with wound healing could be serious if the femorotibial joint is involved.

Injury of the Origin of Gastrocnemius

See Chapter 80.

Hematoma in the Stifle Region

The stifle region is vulnerable to external trauma, particularly when horses jump. Profound injuries to vital structures may result, but frequently external trauma causes only superficial bruising or a subcutaneous hematoma. The clinician's task is to differentiate between a swollen stifle that has a potentially career-threatening injury and one that has a superficial lesion such as a hematoma.

Signs and Diagnosis

A hematoma is manifested as a variably sized swelling, usually on the cranial aspect of the stifle, and may take several hours to reach maximum size. Smaller swellings may be difficult to differentiate from femoropatellar joint effusion. A hematoma is only painful on palpation until the initial bruising and swelling have settled. An uncomplicated hematoma does not usually cause lameness once the discomfort associated with the initial bleeding has passed. Other concurrent injury should be suspected if the horse is substantially lame, especially if lameness persists for several days. A hematoma may occasionally involve only the stifle initially but appears to spread to the inguinal and ventral abdominal areas. Huge swellings can cause oozing from the skin and skin loss. A careful search should be made for open wounds, which could lead to infection in the hematoma or cellulitis. Cellulitis usually takes at least 24 hours to form, and the swelling is firmer than a hematoma, hot, and painful. Lameness worsens as infection progresses.

Ultrasonography is a helpful tool for diagnosing hematoma, which can be confirmed by centesis of the swelling using aseptic technique. In the early stages, frank blood is retrieved, but as the blood clots, the fluid collected will be serum. Radiographic examination is indicated if lameness is severe or persists.

Treatment

In the initial phase, when hemorrhage is likely, the horse should be confined and cold applied to help to slow hemorrhage. Phenylbutazone can be given for its antiinflammatory effect. Antibiotics should be administered if the horse has an open wound. Although some clinicians believe that draining these hematomas is contraindicated, in my experience hematomas resolve better after effective drainage. Drainage should not be attempted until the hemorrhage has stopped and the free blood has clotted, usually 3 to 4 days after the injury. A 2- to 4-cm scalpel incision at the most dependent point of the hematoma ensures that drainage continues until the cavity has filled in.

Prognosis

In the absence of concurrent injury or infection and once the hematoma has resolved and is free of fluid, the prognosis for athletic use is good.

Chapter 47

The Thigh

Dan L. Hawkins and Mike W. Ross

■ THE GLUTEAL SYNDROME

Dan L. Hawkins

Pain that can be demonstrated with digital pressure along a line between the wing of the ilium and the greater trochanter of the femur was first recognized as a cause of lameness more than 50 years ago.¹⁻³ Various aspects of the origin, diagnosis, and management of the syndrome have been appreciated since its initial recognition by Dr. Churchill and myself.^{1,5} The condition has also been referred to as *sacrosciatic lameness* or *pelvic myositis*. We prefer to use the term *gluteal syndrome* because we believe that there may be more than one abnormality that will result in this type of pain.

Gluteal syndrome has been diagnosed in most breeds and uses of horses. Standardbred (STB) racehorses seem to have the highest incidence, but it is not uncommonly seen in Thoroughbred (TB) and endurance racehorses. One risk factor for STBs is related to the more recent harness and race bike designs that tend to decrease the weight borne by the forelimbs while transferring weight to the hindlimbs. Gluteal syndrome has been diagnosed in horses that are used for hunting, jumping, and eventing.

Based on dissections of cadavers, the accessory head of the middle gluteal muscle was identified as the deep structure that best corresponds anatomically to the characteristic pattern of pain. This muscle originates on the concave surface of the wing of the ilium near a tuber coxae. At its caudal extent, the accessory head of the middle gluteal muscle forms a flat tendon that passes over the cranial aspect of the greater trochanter of the femur and inserts on the crest below it. The accessory head is directly related to other aspects of the middle gluteal and superficial gluteal muscles superficially and is important in propulsion of the hindlimbs⁶ (Figure 47-1).

The pathological process associated with the accessory head of the middle gluteal muscle is uncertain. It is known that in horses with some acute injuries a hematoma may form in the area between the ilium and the greater trochanter of the femur. Small, hypoechogenic areas may be demonstrated ultrasonographically in muscle tissue in the same area. In other horses, the muscle may become partially detached from the ilium. Horses with the latter condition develop a depression in the musculature caudal to a tuber coxae after the acute stage. In horses with chronic pain, the affected muscle mass may become very firm, presumably as a result of fibrosis. Post mortem evaluation of two horses with chronic refractory gluteal syndrome did not provide any conclusive information. Other potential changes such as fasciitis, gluteal tendonitis, or injury to one or more adjacent muscles have been considered. Whatever the cause, the source of pain is consistently confined to the area described.

To date, the most reliable, practical method of diagnosis is by careful, systematic physical examination of the area between the wing of the ilium and the greater trochanter of the femur with the horse standing on the limb. More specifically, the musculature should be palpated and examined for changes in resilience, swelling, or fibrosis. The position and outline of the tuber coxae should be evaluated. Next, gentle, deep pressure should be applied along the entire area described with the tips of eight digits (Figure 47-2). Initially, light digital pressure should be applied, but then the pressure is gradually increased to firm, deep pressure. The pressure is maintained briefly to evaluate the horse's response. Finally the area caudal to the ilium, the central portion, and the caudal part of the accessory head of the middle gluteal muscle should be examined similarly. Each third of the area should be considered separately to determine whether the area is affected generally or whether

Fig. 47-1 • Drawing of the anatomy of the lateral pelvic and proximal thigh regions showing the accessory head of the middle gluteal muscle, the most likely source of pain associated with gluteal syndrome. The tendon of the accessory head of the middle gluteal passes over the cranial portion of the greater trochanter, where there is a bursa. Inflammation in this region causes trochanteric bursitis.

Fig. 47-2 • Careful palpation for pain is the only way to establish the clinical diagnosis of gluteal syndrome.

the injury is confined to one or more sections. An unaffected horse will not respond to the examination of any of the areas. An affected horse leans away from the pressure while showing a reluctance to voluntarily bear full weight on the limb as long as the pressure is maintained. A positive response for this syndrome as described is specific and should not be confused with that for trochanteric bursitis (see [Trochanteric Bursitis](#) section).

Most horses with acute gluteal syndrome tend to drag the toe of the affected limb on the ground at a walk. Horses with chronic gluteal syndrome do not drag the toe at a walk, but at a slow trot they break over on the inside of the toe and swing the leg medially and then laterally, finally landing on the outside branch or toe of the shoe. At this gait the lameness produced appears identical to that caused by trochanteric bursitis or tarsitis. When the horse trots, paces, or runs at high speed, the abnormality starts off as described, then the limb appears to tire and is carried more in abduction the further in the race or competition the horse proceeds. It appears that early in the race the horse is able to tolerate the gluteal pain and continue to use the limb for propulsion. However, with sustained speed or intensity of effort over distance, compensatory mechanisms within the limb fatigue as pain from the gluteal injury becomes overwhelming. At this point, a STB may make a break or freeze on a line; a TB may bolt or stop trying in the race; and a show horse may refuse to jump or crash when it tries. Many of these horses are believed to have a stifle problem because the quadriceps muscles fasciculate when they pull up. Others are believed to have exercise-induced pulmonary hemorrhage because they stopped like a bleeder, but no blood is seen endoscopically. Regardless, speed, intensity of work, and distance are key factors in how this problem affects an athletic horse. Some horses that accommodate to the injury or are treated and do not recover to total soundness can perform reasonably well at slower speeds or less intense work.

There is not a specific cause for gluteal syndrome. The onset is frequently directly associated with being cast in a stall, slipping or falling while playing in a paddock, or going down in a trailer or van and struggling to get up while the head is tied. Gluteal syndrome also develops when there is a chronic, preexisting problem in the distal aspect of the same limb, such as hock lameness, suspensory desmitis, or other problem that causes the horse to carry its weight on the toe at high speed. Slipping or losing footing on a soft racetrack or other muddy surface is also associated with development of the clinical signs.

Horses with this injury are best treated while in moderate, controlled exercise, regardless of the treatment approach. Rest alone, even for extended periods, has not been successful as a treatment. Several weeks of careful exercise management with repeated evaluations provide the best chance for a favorable response to treatment. Horses with acute injury, hemorrhage, and severe lameness should be rested until they are walking well and the seroma has resorbed before resuming exercise and treatment. Intramuscular injections of a counterirritant, acupuncture, and extracorporeal shock wave therapy are the best treatment options. At present, I still believe that injections of a counterirritant into the area of sensitivity yield the best results in the shortest time. The injection site is prepared with a surgical scrub followed by rinsing with 70% isopropyl

Fig. 47-3 • Diagrammatic representation of the injection pattern for intramuscular injections of counterirritant solution to manage gluteal syndrome. The dashed lines (1, 2, and 3) provide a grid to guide injection into 20 sites.

alcohol. An injection grid is marked on the horse by drawing three lines in the wet hair over the accessory head of the middle gluteal muscle ([Figure 47-3](#)). One hundred milliliters of 2% iodine diluted in sesame oil solution is injected intramuscularly into 20 sites (5 mL/site) on and between the grid lines with a 4-cm, 19-gauge needle. If the pain is concentrated in the cranial or caudal third of the area between a tuber coxae and the ipsilateral greater trochanter of the femur, the injection sites can be limited to the cranial or caudal half of the area, respectively. After injection, daily moderate, controlled exercise is recommended beginning the day after injection for all horses. After injection, horses with acute or recent gluteal syndrome are walked and jogged for 3 weeks and then reexamined. If the lameness is improved but the area is still sensitive or if there has been no improvement, the injection is repeated in the same manner. Horses with chronic gluteal syndrome are walked and jogged for only 1 week before light training is resumed. Some horses respond dramatically to the treatment and appear to be pain-free within less than a week. The injury cannot heal within that time frame; therefore the temptation to resume full training too quickly must be resisted. When the treatment is successful and horses return to full work and racing, 10% to 20% may experience a recurrence of the problem. These horses generally respond well to an additional treatment as they did previously.

Lameness that fails to improve after two or three injections at 3-week intervals is considered refractory to this mode of treatment. For these horses, I suggest that the trainer or owner try another form of treatment, such as therapeutic ultrasound, acupuncture, or shock wave therapy. Approximately 10% to 15% of horses do not respond to any mode of treatment and never recover from the injury. The prognosis is guarded initially for unilateral injury and poor if the problem is bilateral or if there is a

chronic condition more distally in the same leg. In these horses with more complicated injuries, failure is related to the aggravating effect of each injury on the other.

Shoeing can be a factor in the management of the gluteal syndrome. Slipping on the racetrack, cross-country course, or show jumping arena is a major factor in development and recurrence of the injury. I recommend that TB racehorses that have or have had this condition be shod with block heels on both branches of each hind shoe. Calks applied near the end of both branches of the hind shoes during training and competition can be used in other types of horses.

■ TROCHANTERIC BURSTITIS

Dan L. Hawkins

Pain elicited by firm digital pressure over the greater trochanter of the femur and the musculature immediately caudal to it is attributed to inflammation of the trochanteric bursa and is a cause of lameness in horses.^{1,2} Historically this condition has been referred to as *trochanteric bursitis*, *trochanteric lameness*, and *whorl bone lameness*.⁷ Anatomically the bursa is interposed between the flat tendon of the accessory head of the middle gluteal muscle and the cranial portion of the greater trochanter, which is covered with cartilage at this point. The tendon inserts on the crest below the greater trochanter (see Figure 47-1).⁷

Although confident, positive diagnosis is achieved by physical examination in almost all horses, a technique of injection of local anesthetic solution into the bursa has been described (see Chapter 10).⁸ The condition is relatively common for all breeds and uses of athletic horses and is generally considered to be a secondary problem. Trochanteric bursitis often is associated with tarsitis or other problems in the affected limb in which the horse lands on the toe. An additional cause that has been overlooked is that associated with overreaching with the hindlimbs to compensate for a chronic problem in the forelimbs. A horse that is chronically sore in front (e.g., navicular disease) will try to carry more of its weight on the hindlimbs by overextending the ipsilateral limb, which results in excessive strain on the tendon of the middle gluteal muscle. Wet, cold weather conditions appear to have a positive association with the incidence and response to treatment.

Trochanteric bursitis causes a gait abnormality that is similar to that produced by tarsitis or other sources of pain causing lameness in the distal aspect of a hindlimb. A horse with purely trochanteric lameness breaks over on the medial aspect of the toe; carries the leg medially, even crossing the midline; and then moves the leg laterally to land on the lateral aspect of the toe and branch of the shoe. The length of stride is shortened, and the hindquarters are carried toward the opposite side, which is sometimes described as “dog trotting” at a slow gait. Trochanteric lameness especially affects horses when they are racing around turns, jumping, circling, or performing precision dressage movements.

Trochanteric bursitis is generally a chronic condition that is diagnosed at the same time as a primary condition in the lower limb or ipsilateral forelimb. The more distal condition should be addressed before the bursitis is treated. Occasionally trochanteric bursitis is identified

Fig. 47-4 • Diagrammatic representation of the injection pattern (black circles) to manage horses with trochanteric bursitis.

without an associated primary condition, or it may spontaneously resolve after correction of the associated primary lameness.

Rest is of no value in treating horses with trochanteric bursitis and may intensify the lameness when the horse returns to training. The most effective, practical treatment of trochanteric bursitis is injection of the soft tissues over and around the bursa with a counterirritant solution. The area for injection is prepared with a surgical scrub followed by rinsing with 70% isopropyl alcohol. Approximately 6 mL of 2% iodine diluted in sesame oil solution should be injected into eight sites with a 4-cm, 19-gauge needle (Figure 47-4). The horse should be maintained with mild, controlled exercise for 1 week before resuming normal work. Normally within 5 to 7 days after treatment the horse should become sound behind and no longer resent palpation over the bursa. Horses that require reinjection are more commonly encountered during cold, wet climatic conditions. The prognosis is good for obtaining a cure for trochanteric bursitis provided the associated primary lameness is corrected. Alternatively, solutions of a corticosteroid can be injected in the same manner. In my experience, injection of corticosteroids directly into the bursa is not necessary to alleviate the lameness.

Trochanteric bursitis has been addressed here as a performance-limiting condition in the athletic horse. Trochanteric bursitis that results from external trauma, infection associated with a wound, or a fracture of the greater trochanter of the femur is not discussed.

FRACTURES OF THE FEMUR

Fractures of the femur occur most commonly in foals and weanlings, although they may be seen in older horses. Most femoral fractures result from external trauma, such as a kick or fall with the limb in adduction or abduction. In young foals, fractures may be associated with breaking

to lead. In most horses the traumatic incident is not witnessed, but the horse is found with an unstable, non-weight-bearing lameness in the affected hindlimb. Because of the energy required to fracture the femur of an adult horse, the fracture generally has a severely comminuted configuration. Although foals and weanlings most commonly acquire diaphyseal femur fractures, fractures involving the proximal or distal femoral physis are not uncommon. Salter-Harris type II distal femur fractures are most commonly seen in older weanlings and yearlings.

Diagnosis

In most horses, the diagnosis can be made after a brief physical examination. Femoral fractures result in an acute onset of severe lameness, with swelling in the area of the femur. Swelling occurs rapidly and is generally profound, particularly in adult horses with comminuted fractures. Degree of swelling can be used to differentiate fracture location (see Figure 5-12). Horses with pelvic fractures rarely develop swelling in both the medial and lateral aspects of the thigh, although horses with fractures of a tuber coxae may develop swelling of the proximal, lateral aspect of the thigh. Rotational instability is elicited when internal or external rotation is applied by grasping the proximal tibia and calcaneal tuber. Crepitation may be appreciated with manipulation of the limb. However, swelling and hemorrhage in the large muscle mass of the thigh may keep the fracture ends separated and make it difficult to elicit crepitus. The large muscle mass also makes open fractures uncommon. Swelling is most consistent with diaphyseal fractures, but it is often less obvious with proximal physal fractures and minimally displaced distal

physal fractures. In most horses, the distance between reference points, such as the patella and the greater trochanter of the femur, is shortened because of the overriding of the fracture fragments that is caused by contraction of the quadriceps muscles. Foals with proximal physal fractures may be able to bear some weight on the affected limb.

Radiological evaluation is required to obtain a definitive diagnosis and determine the severity of a femoral fracture (Figure 47-5). Radiography of horses larger than young foals requires use of general anesthesia unless the fracture is located in the distal aspect of the femur. Many small foals can undergo radiography safely when recumbent under heavy tranquilization or general anesthesia. Because induction and recovery of large yearlings and adults cannot be assisted sufficiently to prevent complications and discomfort, general anesthesia is contraindicated for assessment of unstable femur fractures. Ultrasonography can be used to confirm a displaced femoral fracture in a standing horse.

Once the horse is in lateral recumbency with the affected limb down against the cassette and the opposite limb abducted, the x-ray beam should be directed from medial to lateral. Radiography of the diaphysis and proximal aspect of the femur requires a grid and high-capacity x-ray generator except for examination of small foals and the distal aspect of the femur of larger horses. Two exposures are generally required for the mediolateral images because of the variation in soft tissue mass around the distal and proximal aspects of the femur. Craniocaudal images are also required to assess the severity of the fracture and the degree of overriding. Evaluation of the proximal physis requires that the horse be positioned in dorsal recumbency with the cassette and grid under the coxofemoral area.

Fig. 47-5 • Lateromedial digital radiographic images of a left femur. **A**, Initial view of a 2-month-old Thoroughbred filly with a simple, short-oblique, midshaft femoral fracture showing the typical cranioproximal displacement of the proximal fragment and caudodistal displacement of the distal fragment. The fracture was considered closed because there was no obvious communication between a superficial wound from the causative kick and the fracture site; the wound was stapled (stainless steel staples are visible) before admission. **B**, Postoperative image showing internal fixation using a lateral locking compression plate and a cranial limited-contact dynamic compression plate. A closed suction drain is visible. **C**, Radiographic image of the femur 2 years after injury and repair. The now 2-year-old filly was sound. The plates were removed 5 months after surgery; the fracture healed completely; and the stifle and hip (not shown) joints were radiologically normal.

Case Selection for Treatment and Prognosis

The decision to treat horses with femoral fractures by surgical intervention depends on several variables. The size of the horse is the single most important consideration, regardless of fracture type. Successful surgical treatment of diaphyseal or proximal physeal fractures has been accomplished only in foals and small ponies.⁹ Distal physeal fractures have been successfully repaired in yearlings.^{10,11} However, adult horses or young horses weighing more than 200 kg (440 lb) with displaced diaphyseal fractures warrant humane destruction.¹² Fracture location and configuration, soft tissue injury, temperament of the horse, client expectations, and economic considerations are other important determinants for case selection. Compromise of the vascular supply caused by the fracture, damaged major vessels, and swelling can result in failure because of necrosis of the distal aspect of the limb.¹³

Surgical techniques, complications, and the prognosis for horses with diaphyseal and proximal and distal physeal femoral fractures were reviewed.^{9,12,14} Of foals with diaphyseal fractures that were repaired with double plating, 50% of the fractures healed, and 75% of the horses were able to perform the intended use.¹⁵ The most common complications were seroma formation and infection. Foals with a successful outcome were younger than 3 months of age (see Figure 47-5). Additionally, an intact caudal cortex was considered necessary for a successful outcome. Newly designed implants such as the locking compression plate (LCP) may improve prognosis and make possible successful surgical repair in older horses or in those with comminuted fractures because stable anatomical alignment, exact contouring of the plate to bone, and compression of the plate to bone are not needed (see Figure 47-5).¹⁶ Successful outcome was achieved in two foals with open, comminuted femoral fractures repaired using two LCPs and a combination of locking and conventional cortex bone screws.¹⁶ Conservative management of horses with diaphyseal fractures can result in fracture healing. However, limb shortening, rotational deformity, and serious varus deformity in the contralateral limb are common complications of this approach. The prognosis of horses with distal fractures was more guarded than that for diaphyseal fractures because of the limited amount of bone for implant purchase. Success of the condylar screw plate for repair of a distal femur Salter-Harris type III fracture in a 2-year-old horse suggests this implant has application in repair of selected distal femoral fractures in horses.¹⁷ Conservative management of horses with distal fractures can result in a satisfactory outcome if the fracture is minimally displaced and stable.¹⁵

Although proximal femoral physeal fractures account for 16% of physeal fractures in the horse,¹⁸ sufficient reported results of surgical treatment to establish good prognostic information are lacking. Currently the prognosis for successful repair is guarded at best. Conservative management is unlikely to result in a comfortable horse. Unstable fixation, necrosis of the femoral head, and osteoarthritis of the coxofemoral joint are the more common complications associated with failure of surgical or conservative approaches.

Other less common types of proximal femoral fractures that cause less severe lameness in older horses include the third trochanter (see Chapter 50) and greater trochanter.

Ultrasonography is helpful in confirming these fractures. Unless horses with these fractures have an associated wound or bone becomes sequestered, they should be managed with stall rest.⁹ Stress fractures of the femur are rare but occasionally occur in the proximal cranial femoral cortex.

FIBROTIC AND OSSIFYING MYOPATHY

See Chapter 48 for a discussion of fibrotic or ossifying myopathy.

GASTROCNEMIUS MUSCLE INJURY

See Chapter 80 for a complete discussion of gastrocnemius muscle injury. Injury of the origin of the gastrocnemius can cause acute, severe hindlimb lameness in foals and adult horses. The diagnosis is straightforward when the reciprocal apparatus is disrupted, the most common clinical presentation in foals. Of six foals with gastrocnemius rupture, five had a history of dystocia and assisted delivery (three in a hip-locked position); four foals had complete disruption of the reciprocal apparatus and were unable to rise; life-threatening hemorrhage into the gastrocnemius muscle occurred in one foal, and concurrent perinatal diseases complicated management; and neither of the two foals discharged from the hospital were sound for athletic use.¹⁹ Successful restoration of the reciprocal apparatus after rupture of the gastrocnemius and superficial digital flexor muscles was achieved in a 6-month-old Warmblood filly using a modified Thomas splint-cast combination.²⁰ The prognosis is grave when there is complete disruption of the reciprocal apparatus in adult horses. However, partial tearing at the origin of the gastrocnemius, musculotendonous junction, or more distally near or at the attachment on the calcaneus can occur and cause moderate hindlimb lameness that is difficult to diagnose. A peculiar gait is seen in some horses with gastrocnemius origin and tendon injury. Horses appear to have difficulty maintaining stability of the limb during late stance phase and when pushing off and exhibit marked internal rotation of the distal limb with lateral rotation of the point of the calcaneus.²¹ Some horses exhibit this type of hindlimb movement normally, but it is symmetrical and not accompanied by lameness. I have seen this peculiar gait in other horses with caudal thigh pain such as fracture of the tuber ischium with avulsion injury of the caudal thigh muscles. Gastrocnemius origin injury can be challenging to diagnose, but increased radiopharmaceutical uptake and bony proliferation were found in three of four horses,²¹ and ultrasonographic examination using comparative images of the contralateral limb is necessary, particularly in horses with injury of the more distal aspects of the gastrocnemius musculotendonous junction and tendon.

Gracilis Muscle Injury

Although unusual, acute severe lameness and swelling of the medial thigh occur as a result of gracilis muscle injury. Gracilis muscle injury caused substantial hindlimb lameness in two barrel racing horses; the site of injury was confirmed using local infiltration into the affected muscles, and ultrasonographic examination confirmed injury.²² One horse developed an unusual gait consistent with

fibrotic myopathy that resolved after resection of scar tissue.²² In this report, both horses returned to athletic use.²² Gracilis muscle injury is seen in polo horses (see Chapter 119, page 1164).

Other Thigh Injuries

Generalized muscle injury can cause acute swelling of the medial aspect of the thigh and pronounced lameness. Rarely, swelling, lameness, and fever are found in horses that develop abscesses in the medial thigh or inguinal region. Ultrasonographic examination for diagnosis,

surgical drainage, and appropriate antimicrobial and anti-inflammatory therapy are necessary. A horse with swelling of the thigh, fever, and sudden death was diagnosed with a dissecting aortic aneurysm.²³ Large, dissecting hematomas from direct trauma may originate near the stifle and extend into the medial and sometimes the caudal aspects of the thigh and may require surgical drainage. Fractures of the tubera ischii, tubera coxae, and rarely luxation of the coxofemoral joint can cause swelling of the thigh. These conditions are discussed in detail in Chapters 49, 50, and 126.

Chapter 48

Mechanical and Neurological Lameness in the Forelimbs and Hindlimbs

Sue J. Dyson and Mike W. Ross*

GENERAL CONSIDERATIONS

Mechanical lameness reflects altered biomechanical forces affecting limb function. The biomechanics of limb function depend on normal functioning of peripheral nerves, muscles, tendons, and ligaments. Appropriate muscle contraction and relaxation are important factors in limb biomechanics. A muscle that cannot contract with sufficient force or a muscle that cannot relax and stretch can result in an altered gait. Mechanical lamenesses are typically most obvious at the walk and often become less evident or disappear at the trot. Gait alterations may not be evident at the canter, although a horse with a mechanical lameness may not be capable of generating a smooth canter and may appear to be hopping or “off” behind at the canter. Mechanical lamenesses include altered gaits caused by decreased and increased joint flexion.

The importance of proper functioning of the neuromuscular system for a normal hindlimb gait is exemplified by horses with chronic motor neuron disease and myopathy from equine polysaccharide storage myopathy (EPSSM). Both of these neuromuscular disorders can be associated with a fibrotic myopathy-type or stringhalt-type of gait. Horses with EPSSM may develop prolonged or intermittent upward fixation of the patella. Underlying myopathy was found in some but not all horses with shivers (shiverers).^{1,2} Neuropathy is known to be a cause of stringhalt^{3,4} and was found in horses with fibrotic myopathy.⁵ Trauma to

peripheral nerves may also cause a mechanical lameness. The possible role of altered proprioceptive input to the affected limb is intriguing and is discussed under appropriate headings.

Equine protozoal myelitis or myeloencephalitis (EPM) with involvement of motor neurons causing selective denervation may also cause mechanical lameness. In horses with EPM, lameness cannot be abolished using diagnostic analgesia. Horses with lameness from EPM should, however, also exhibit proprioceptive deficits and ataxia and usually exhibit muscle atrophy. Lameness in horses with EPM may be caused by pain arising from atrophied muscles, nerve root pain, or pain originating from peripheral nerves. EPM is unlikely to cause an obvious mechanical lameness without accompanying ataxia. It is difficult to accept that EPM could cause selective damage to motor neurons sufficient to cause a mechanical lameness without also causing concurrent spinal cord white matter damage and ataxia, but it does do so occasionally, and neurological deficits may be subtle early in the disease. Careful neurological evaluation by a clinician with expertise in equine neurological evaluation is an important part of examining a horse with mechanical lameness because distinguishing between gait abnormality caused by mechanical lameness and gait abnormality caused by neurological disease may be difficult.

Electromyography and muscle biopsy may aid in determining the cause of mechanical or neurologically mediated lameness. Concentric needle electromyography of denervated muscle often reveals abnormal spontaneous activity such as positive sharp waves, fibrillations, and myotonic bursts. Abnormal spontaneous activity may also be present in muscles of horses with myopathy, but these findings are generally mild and may be absent. Biopsy of the semimembranosus or semitendinosus muscle is useful for evaluating evidence of denervation atrophy and EPSSM. However, if denervation of a single muscle or part of a muscle causes the gait alteration, sampling error may result in a false-negative result.

Mechanical lameness does not always cause pain, and horses usually do not respond to nonsteroidal antiinflammatory drug therapy. Methocarbamol therapy is indicated only when muscle cramping from central nervous system disease is suspected. Phenytoin therapy has proved to be useful in some horses with mechanical lameness, particularly those with stringhalt.

Mechanical lameness in the horse is the result of abnormal structure or function of the musculoskeletal system or,

*The authors of this chapter acknowledge and appreciate the contribution of Beth A. Valentine, who authored this chapter in the previous edition.

more commonly, of the neuromuscular system. Possibly a variety of underlying problems can result in the same type of mechanical lameness. Limb dysfunction may also be caused by an imbalance of flexor and extensor muscle activity as a result of a primary neurological cause.

ANATOMICAL CONSIDERATIONS

A number of unique anatomical features in the equine hindlimb contribute to mechanical lameness. The configuration of the patellar ligaments in the stifle joint allows locking of the stifle into an extended position (see page 94). The stay apparatus minimizes the muscular effort required for a horse to stand for long periods. The reciprocal apparatus links the actions of the stifle and hock, primarily through the fibularis (peroneus) tertius and superficial digital flexor tendons, such that an abnormal action in either joint affects the action of both.

Innervation patterns to the muscles of the hindlimbs may also contribute to mechanical lameness. The semitendinosus muscle, for example, receives innervation from two different nerves: the caudal gluteal and sciatic nerves. Often more than one muscular branch innervates long muscles such as the semitendinosus and possibly the semimembranosus. Damage to one nerve or to a muscular branch can result in partial denervation of a large muscle, with resultant altered biomechanical forces leading to abnormal limb action.

UPWARD FIXATION OF THE PATELLA (LOCKING STIFLE) AND DELAYED RELEASE OF THE PATELLA

Clinical Characteristics

Horses and ponies with upward fixation of the patella are episodically unable to flex the stifle or the hock and drag the extended limb behind them on the toe (see Figures 5-18 and 48-1). The condition occurs most commonly after a period of standing still and tends to decrease with continued exercise. An intermittent form of patellar fixation, called *delayed release of the patella*, also occurs, in which the patella appears to catch briefly, sometimes followed by exaggerated flexion of the stifle and hock. Low-grade intermittent upward fixation or delayed release of the patella is relatively common, but it is often difficult to detect and is not necessarily observed daily. Affected horses have a slightly jerky movement of the patella that may be most apparent during deceleration from trot to walk and when the horse is working in deep footing, especially on turns. Affected horses may appear to be in some discomfort, may be resistant to work especially in deep footing, and can become irritable. Both upward fixation of the patella and delayed release may occur unilaterally or bilaterally. Fifty-five of 78 horses (70.5%) with upward fixation of the patella were affected unilaterally and 23 (29.5%) bilaterally.⁶

Warmbloods, Thoroughbreds, Standardbreds, and some pony breeds (e.g., Shetland and Miniature ponies) may be predisposed to upward fixation of the patella.⁶ The episodic nature of intermittent upward fixation of the patella adds to the difficulty of detecting an affected horse. Careful observation while moving the horse over from side to side, turning in small circles, or walking down an incline can be particularly useful. Clinical signs of upward fixation of the

patella or delayed release of the patella are most commonly seen in young horses, especially those kept stabled, and signs may diminish or disappear if the horse becomes fitter and stronger. However, clinical signs may recur if the horse is confined to box rest for an unrelated reason. Persistent upward fixation of the patella has also been described in a foal.⁷

Cause

Upward fixation of the patella has been attributed to abnormal laxity and to increased tenseness of patellar ligaments. Decreased force of muscle contraction of the thigh muscles (quadriceps and biceps femoris) that move the patella out of the locked position may also cause upward fixation of the patella. This may be the explanation for upward fixation of the patella occurring in unfit horses, those in poor condition, or those with underlying myopathy, causing weak or stiff muscles. Horses and ponies with overly straight hindlimbs may be prone to upward fixation of the patella because such conformation can result in overextension of the stifle joint, leading to patellar locking.^{6,7} Sixteen of 78 horses (20.5%) with upward fixation of the patella had straight hindlimb conformation.⁶ Foot conformation may also play a role. Thirty-one of 78 horses (39.7%) had long toes and/or a higher inside wall of the hind foot of the affected limb(s).⁶ Permanent upward fixation of the patella occurs rarely secondary to luxation or subluxation of the ipsilateral coxofemoral joint (see Chapters 50 and 126).

Biomechanical Basis

Upward fixation of the patella is caused by failure of the medial patellar ligament to unhook from the medial ridge of the femoral trochlea, causing the stifle to lock in extension. Abnormalities of the fibrocartilage at the medial aspect of the patella also possibly make the joint prone to locking. Once the stifle is locked in extension, the hock is also fixed in extension through the action of the reciprocal apparatus. The biomechanical basis for stifle hyperflexion after the brief period of patellar catching in intermittent upward fixation of the patella (or delayed release of the patella) is not entirely clear and may be from increased force of contraction of the biceps and quadriceps muscles during the transient locking phase. Clearly, therapy for this disorder should be directed at correcting the underlying cause. Unfortunately, for many horses an exact cause is never determined.

Medical Therapy

Exercise is an important part of therapy for horses with upward fixation of the patella. Conditioning exercise, including work on hills, may result in complete resolution of the problem in some horses. Uphill work may be more beneficial than downhill exercise. Horses that respond to conditioning exercise indicate that muscle dysfunction can play an important role in the development of upward fixation of the patella. Corrective trimming and shoeing is also important; the toe should be shortened to facilitate breakover, and mediolateral imbalance should be corrected. It has been suggested that rounding the medial aspect of the foot to promote medial breakover may be beneficial together with elevation of the lateral heel using a wedge-heel shoe.⁶ Thirty-three of 64 (51.6%) horses with upward

Fig. 48-1 • Diagrammatic representation of the common mechanical hindlimb gait abnormalities. **A**, In horses with upward fixation of the patella, the hindlimb is periodically held in rigid extension. The fetlock joint is flexed, and the horse walks on the toe. Horses with intermittent upward fixation can have a gait similar to shivers (see **D**). **B**, Horses with fibrotic myopathy show slapping of the affected hindlimb downward just before the end of the cranial phase of every walk stride. Hock flexion is near normal, but fibrous tissue in the caudal thigh region limits the cranial phase of the stride. **C**, Horses with stringhalt exaggerate flexion of the hock with the hindlimb in a normal (adducted) position. This gait occurs at every walk stride. Excessive hock flexion causes some horses to hit the ventral abdomen with the dorsum of the hindlimb. **D**, Horses with shivers often have abnormal tail head elevation and hold the affected hindlimb in a flexed and raised position away from the midline (abducted). This abnormal gait occurs sporadically, not at every walk step, which helps to distinguish it from stringhalt.

fixation of the patella had a successful outcome following corrective trimming and shoeing, dietary management to promote better condition, and exercise, and a further 13 (20.3%) improved.⁶

If underlying myopathy such as EPSSM is the cause, diet change to one that is high in fat and low in starches and sugars⁹ and continued exercise conditioning may be beneficial. The most effective diets are those that provide at least 20% to 25% of total daily energy from fat and less than 20% of total daily energy from starches and sugars.

Another medical therapy is administration of estrogenic compounds. The rationale is presumably that estrogens can cause tendon and ligament relaxation. Whether horses with upward fixation of the patella have overly tense patellar ligaments and whether estrogen has any effect on patellar ligaments and tendons are unclear. Estrogen effects on muscle cell metabolism and muscle tone are possible. Anecdotal evidence suggests that some horses may benefit from this type of therapy. Intramuscular injection of 1 mg of estradiol cypionate per 45 kg of body weight (i.e., 11 mg/500 kg) once weekly for 3 to 5 weeks has been recommended.

Fig. 48-2 • **A**, Lateromedial digital radiographic image (*cranial is the right and proximal is uppermost*) of the right stifle joint in a 7-year-old Warmblood gelding with bilateral hindlimb lameness. This horse had instability of the hindlimb characterized by knuckling after bilateral medial patellar desmotomy and the subsequent development of distal patellar fragmentation, bilaterally (*arrow*). **B**, Intraoperative arthroscopic photograph (*lateral is to the right and proximal is uppermost*) showing fragmentation (*arrows*) of the distal aspect of the left patella (*P*). The underlying lateral trochlear ridge (*LTR*) of the distal femur can be seen. The fragments were removed from both stifle joints.

Injection of iodine-containing counterirritants into and around the medial and middle patellar ligaments has also been advocated.¹⁰ It has been proposed that maturation of a fibrous and inflammatory response may result in stiffening of the ligaments and thus relieve upward fixation of the patella.¹¹ Injection of a 2% solution of iodine in oil or of ethanolamine oleate has been advocated. Injection of 1 to 1.25 mL of these compounds into numerous sites in and around the distal aspect of the medial and middle patellar ligaments is recommended. However, in an experimental study in normal horses, injection into the medial and middle patellar ligaments with iodine in almond oil provoked more fibroplasia and infiltration of inflammatory cells than ethanolamine.¹¹

Surgical Therapy

Medial patellar desmotomy may be necessary, although this should be considered only in horses with upward fixation of the patella that is unresponsive to conditioning exercise or medical therapy, or for horses that are persistently locked for several days. Because the transected ligament eventually heals with a fibrous union, the main benefit of surgery may be temporarily to alter the action of the stifle joint such that the horse is capable of conditioning exercise. Development of fragmentation of the apex of the patella (sometimes referred to as patellar chondromalacia) and associated lameness may occur after medial patellar desmotomy, although rest for 3 months postoperatively may reduce the risk (see Figure 46-4) (Figure 48-2).¹² Treatment of fragmentation of the apex of the patella is by arthroscopic debridement (see Chapter 46). Middle patellar desmitis is also a potential untoward sequela.^{6,13} Occasionally after medial patellar desmotomy persistent lameness develops from residual desmitis, swelling and inflammation, or osteitis of the patella. One of us (MWR) has seen

horses develop instability and knuckling of the hindlimb after medial patellar desmotomy. Percutaneous splitting of the medial patellar ligament may be equally effective, with less potential for secondary fragmentation of the apex of the patella.^{14,15} Twenty-three horses were treated by ligament splitting without complication,¹⁵ whereas eight of 18 horses (45%) treated by desmotomy had secondary stifle-related lameness, despite many being rested for 3 months postoperatively.⁶ A modification of the originally described technique for medial patellar splitting (desmoplasty) can be equally effective.^{16,17} Briefly, in a standing horse after sedation and the injection of local anesthetic solution subcutaneously over the involved medial patellar ligament(s), a 14-gauge, 4-cm-long needle is used to perform desmoplasty. The needle is inserted through skin at three locations (proximal, midligament, distal), and four to nine desmoplasty incisions, in roughly a cranial-to-caudal direction, are made in a fan-shaped fashion.^{16,17} One of us (MWR) has used 12 to 15 deep incisions, and although I was initially skeptical of efficacy, I have been impressed with resolution of clinical signs soon after the procedure, even in horses that are almost persistently locked. Horses are maintained on phenylbutazone, and the femoropatellar joint is medicated with hyaluronan and short-acting corticosteroids.

Identification of a chronically thickened medial patellar ligament at a clinical examination for an unrelated reason (e.g., a prepurchase examination) usually reflects previous medial patellar desmotomy or splitting.

FIBROTIC MYOPATHY

Clinical Characteristics

The gait of fibrotic myopathy is characterized by a shortened cranial swing phase of the affected hindlimb while

walking, with an abrupt catching of the forward swing, a slight caudal swing, and slapping of the hoof onto the ground (see Figure 48-1). This abnormal gait is present at every walk stride and has a characteristic sound, but it is often much less apparent at the trot and canter. However, an affected horse appears lame at the trot. The degree of gait impairment varies according to the severity and extent of muscle pathology. Affected horses may have a palpable thickening on the caudal aspect of the crus, which may extend distally and medially toward the tuber calcanei, but this is not a consistent finding. Osseous metaplasia may accompany fibrosis in some horses. Affected muscles may exhibit some degree of atrophy. Some horses have an obvious dimple, scar, or depression in the affected muscle. Ultrasonographic evaluation of the caudal thigh musculature can be useful¹⁸ and may detect focal hyperechogenic areas of fibrosis when none are palpable or hyperechogenic areas with underlying acoustic shadowing associated with mineralization. The proximodistal extent of muscle abnormality can be determined.

Fibrotic myopathy may be more common in Western performance horses and gaited horses. Fibrotic myopathy is most often a unilateral problem but can occur bilaterally. Fibrotic myopathy may occur first in one hindlimb, followed by development of a similar abnormal gait in the other hindlimb months to years later. This gait abnormality does not appear to be painful or distressing to the horse, and signs do not increase from anxiety or decreased ambient temperature. Fibrotic myopathy occurs most often in adult horses but has also been described in neonates. Fibrotic myopathy in foals is not associated with palpable fibrosis of the distal aspect of semitendinosus muscle. Diagnosis is made by recognition of the typical gait abnormality. Occasionally injection of local anesthetic solution into the involved muscle bellies may partially alleviate clinical signs (see Chapter 122).

Cause

Fibrotic myopathy is usually the result of trauma of the semitendinosus muscle during activities that result in extreme tension, such as sliding stops in reining horses and struggling from catching a leg in a halter or tether. Traumatic injuries to the semitendinosus, or inflammatory processes such as abscesses at injection sites, can cause fibrotic myopathy. Less commonly, damage to the semimembranosus or gracilis muscle (see Chapter 47) is a cause.¹⁹ Fibrotic myopathy present at birth has been speculated to be caused by trauma at or soon after birth.²⁰ Adhesions between the semitendinosus and the semimembranosus or biceps femoris muscles causing restriction of muscle action have been proposed.²¹ Careful study of a small series of horses with fibrotic myopathy found that underlying traumatic or degenerative neuropathy causing denervation of the distal semitendinosus muscle can result in fibrotic myopathy.⁵ Two horses with minimal fibrosis had bilateral fibrotic myopathy from degenerative neuropathy of unknown cause. One horse had unilateral fibrotic myopathy caused by nerve damage after fracture and scarring of the caudal aspect of the greater trochanter. This horse had characteristic fibrosis of the distal aspect of semitendinosus muscle. Underlying neuropathy is the most likely cause in horses in which fibrotic myopathy develops in one hindlimb and progresses to involve the other hindlimb.

Biomechanical Basis

Functional shortening caused by muscle scarring, adhesions to adjacent muscles, or denervation results in increased muscle tension that does not allow full extension of the stifle, and secondarily the hock, during the cranial swing phase.

Medical Therapy

No medical therapy has been shown to be consistently useful in treating fibrotic myopathy. In horses with complex muscle injury, such as those that develop fibrotic myopathy after lacerations or other traumatic injuries that involve not only the semitendinosus but the nearby semimembranosus muscle, corticosteroid injections into the fibrotic scars and nonsteroidal antiinflammatory therapy may partially alleviate clinical signs. Short-term improvement is reported in gaited horses with early fibrotic myopathy after injection of antiinflammatory drugs into involved muscles (see Chapter 122). Exercise does not appear to alleviate or exacerbate the abnormal gait.

Surgical Therapy

Surgical resection of the affected distal semitendinosus muscle (semitendinosus myotomy)²² or affected muscle and tendon of insertion (semitendinosus myotectomy)^{19,21} and semitendinosus tenectomy at the tibial and tuber calcaneal insertions²⁰ have all resulted in some degree of immediate gait improvement. However, occasionally no immediate response has been seen, but delayed improvement has been observed following tenectomy.²³ Myotomy and myotectomy have been associated with a relatively high degree of postoperative complications compared with simple tenectomy. If portions of muscle are excised, submission of these samples to a histopathologist with expertise in the pathology of neuromuscular disease may aid in determining the cause. Recurrence and exacerbation of clinical signs after myotomy and myectomy are the most common complications. Occasionally myotomy (fibrotomy) results in appreciable clinical improvement in horses with well-defined scars. At least partial recurrence of fibrotic myopathy after successful surgery occurs in about one third of horses, although the resultant gait deficit may not interfere with full return to function.²² If progressive neuropathy is the cause, recurrence of signs after any type of surgery is likely.

STRINGHALT

Clinical Characteristics

A horse with stringhalt has an exaggerated upward flexion of a hindlimb or both hindlimbs that occurs at every walk stride (see Figure 48-1).²⁴⁻²⁶ The affected limb is brought up and in (adducted) underneath the horse, such that the fetlock may contact the ventral abdominal wall. This abnormal gait often lessens considerably during the trot and usually, but not always, disappears at the canter. Affected horses may have difficulty backing, and the gait abnormality may only be apparent while backing in horses with mild disease. In such horses a diagnosis of mild shivers should also be considered. The Australian form of stringhalt is often bilateral and occurs in groups of horses on pasture containing a plant similar to dandelions known as

flatweed (*Hypochoeris radicata*).³ The toxic principle is as yet unknown. Forelimbs may also be affected in horses with Australian stringhalt. A similar syndrome has been seen in the Pacific Northwest of North America,²⁴ in Europe,²⁶ and in South America.²⁷ In an outbreak in Brazil, plants containing *H. radicata* were fed to a normal horse and mild stringhalt developed, but signs abated when a similar plant from a different location was fed, leading to speculation that plants may vary in toxicity.²⁷ In mice, ingestion of *H. radicata* was associated with a significant increase in a metabolic biomarker, scyllo-inositol, known to be associated with other neurodegenerative diseases from neuronal and glial dysfunction.²⁸ Horses with stringhalt may or may not appear distressed by the gait abnormality. Similar to shivers (see the following discussion), anxiety and cold weather are reported to increase the severity of clinical signs in horses with stringhalt.^{4,24}

Cause

True stringhalt and sporadic, or pasture-associated, stringhalt are most likely caused by underlying neuropathy. The Australian form of stringhalt has been clearly shown to be from underlying neuropathy.³ Some horses with sporadic stringhalt have had evidence of neuropathy and denervation atrophy, although the cause has not been apparent. Histopathological evaluation of the lateral digital extensor muscle after lateral digital extensor myotectomy has been particularly useful in detecting evidence of denervation atrophy. Horses with equine motor neuron disease have generalized denervation atrophy and can develop stringhalt that may be bilateral. Denervation atrophy of numerous muscles of the affected hindlimb is seen in horses with stringhalt from EPM. Careful examination of numerous nerves from horses with sporadic²⁴ or pasture-associated stringhalt³ has revealed widespread neuropathy. Laryngeal hemiplegia associated with stringhalt is common, indicating a predisposition for abnormalities of long nerves. Stringhalt may be a different form of neuropathy than that seen in horses only developing laryngeal hemiplegia because clinical signs in some horses that develop stringhalt spontaneously resolve. Stringhalt may be similar to peripheral neuropathies in dogs, in which long nerves such as the recurrent laryngeal and sciatic nerves can be preferentially involved, and the cause is often not known. Lesions occur in the left recurrent laryngeal nerve in about 60% of horses with Australian stringhalt.³ Clinical signs of laryngeal dysfunction may or may not be apparent. Development of stringhalt has been reported in horses after trauma to the dorsal tarsal and metatarsal regions in the area of the extensor tendons.²⁵ If proprioceptive deficits and ataxia are detected in a horse with stringhalt, peripheral neuropathy caused by EPM should be considered likely.

Biomechanical Basis

Although underlying neuropathy is well established as a cause of stringhalt, the biomechanical basis for the exaggerated flexion is still somewhat perplexing. Altered proprioception from neuropathy was suggested,⁶ and this hypothesis is appealing. In stringhalt, however, the gait deficit appears to be consistently abnormal, stride to stride, unlike that seen in horses with other forms of proprioceptive deficits. Neuropathy may lead to paresthesia or altered

input to or activity of muscle spindles. Given the exaggerated flexion of the hindlimbs of most horses after placement of hindlimb shipping (traveling) boots, altered sensation leading to limb hyperflexion is plausible. Other proposed causes include tendon adhesions around the tarsocrural joint or altered tendon reflexes after trauma²⁴ and hyperexcitability of motor neurons.⁴

Medical Therapy

For horses with stringhalt associated with plant toxicity, removal from the pasture may be curative, although recovery may take months to years and may not be complete.⁴ Trauma-induced stringhalt may resolve with exercise therapy.²⁵ Oral phenytoin at 15 to 25 mg/kg once or twice daily may also be effective in some horses. The beneficial actions of phenytoin may include stabilization of neuronal, peripheral nerve, or skeletal muscle membrane electrical activity or decreased anxiety from sedation.⁴ Botulinum toxin type B was used to reduce anal tone in horses, and it is compelling to consider its use for management of horses with stringhalt and other neuromuscular conditions.²⁹ Horses appear unusually sensitive to the effects of botulinum toxin; therefore caution should be used. In a recent experimental and clinical study, normal ponies (400 IU) and two Warmbloods with stringhalt (700 IU) were injected with botulinum toxin type A into the long digital extensor, lateral digital extensor, and vastus lateralis muscles.³⁰ Surface electromyography revealed reduced surface signals over the injected muscles; there was obvious clinical improvement in the two horses with stringhalt that lasted 12 weeks after injection, and kinematic studies confirmed a reduction in intensity of hindlimb hyperflexion.³⁰

Surgical Therapy

Horses with residual gait abnormality after plant toxicity or traumatic neuropathy and horses with stringhalt caused by degenerative peripheral neuropathy may benefit from lateral digital extensor myotectomy.²⁶ Horses with traumatically induced stringhalt appear to benefit most from lateral digital myotectomy. In some horses, clinical signs may actually gradually worsen after surgery. Resolution of clinical signs after blocking the lateral digital extensor tendon may be a useful response to determine whether myotectomy is indicated (see Chapter 122). In horses with stringhalt in which local anesthetic solution is placed directly into the lateral digital extensor muscle, both of us have observed 50% to 75% improvement in clinical signs, but clinical signs also improve if the cranial tibial and long digital extensor muscles are blocked. Selective blocking of the superficial and deep fibular (peroneal) nerves, the common fibular nerve, and the tibial nerve may help determine etiology in some horses, but the response is inconsistent. Selective peroneal (fibular) neurectomy remains a potential method of surgical management. Although some affected horses may return to full and high-level athletic performance after surgery, for many this should be considered a salvage procedure to allow a more normal gait for breeding horses, pasture pets, and horses in which the owner's expectations of performance are limited to light hacking.

SHIVERS (SHIVERERS, SHIVERING)

Clinical Characteristics

First described in draft breeds, shivering also occurs commonly in Warmbloods. Anecdotal evidence suggests a heritable predisposition. Shivers also occurs sporadically in other breeds, including Thoroughbreds, Quarter Horses, Arabians, and Morgans.

The clinical features of shivers, particularly in horses with early or mild disease, may resemble stringhalt or intermittent upward fixation of the patella. Affected horses may be described as stringy, especially by draft horse owners. Affected horses exhibit an episodic hyperflexion of the hindlimb and often abduct the limb before placing the hoof on the ground (see Figure 48-1). The affected limb may be held up in a flexed and abducted position for several seconds. This is most commonly seen when the limb is picked up. Sometimes the tail is simultaneously raised (Figure 48-3). The horse may stretch its head up or forward during these episodes, and flickering of the eyelids and ears occurs occasionally. The muscles of the affected limb may tremble, and sometimes the tail quivers. Some horses only show clinical signs when the limbs are picked up and have a normal gait under all other circumstances. If an abnormal gait is present, unlike stringhalt it is sporadic rather than occurring at every stride and is not apparent at the trot or canter. The abnormal gait is most often seen when backing, turning tight circles, in the first walk stride after standing, and in the last walk stride before halting. The clinical signs may also be seen periodically while the horse is standing still. Anecdotally, the abnormal gait may be exacerbated by lack of exercise, cold ambient temperature, and increased anxiety in the horse. Neurological examination does not reveal evidence of postural reflex abnormalities or of ataxia.

Fig. 48-3 • Belgian draft horse exhibiting the raised tail and hindlimb overflexion characteristic of severe shivers.

The farrier may first diagnose shivers because trimming and shoeing the hindlimbs is often difficult. The horse may be reluctant or appear unable to hold the affected limb up or to stand on three limbs for any length of time. When asked to lift a hind foot, the horse often hesitates, followed by an exaggerated flexion. Affected horses may appear worried when a hindlimb is picked up. They may be more comfortable if allowed to turn the head and neck toward the limb being picked up.²³

Shivers may be a progressive disorder in some but not all horses. Severely affected horses develop generalized muscle atrophy and weakness and may exhibit periodic cramping of each leg in succession, with occasional leaning of the body such that the horse appears ready to fall. Onset is often between 2 and 4 years of age, but this varies extremely, as does the rate of progression. One of the authors (SJD) is aware of a homebred 10-year-old Warmblood mare that exhibited shivers as a neonate and has continued to show similar clinical signs throughout its life. The most severe form of progressive shivers occurs in draft horses. A somewhat milder form occurs in Warmbloods, in which sporadic abnormal hindlimb action is seen, but Warmbloods with shivers rarely exhibit a raised and quivering tail. Clinical signs in such horses are often mistaken for stringhalt or intermittent upward fixation of the patella. Affected horses can continue to compete at high levels in dressage or jumping for many years. Prepurchase evaluation of these high-performing shiverers can be particularly vexing because the expected progression of signs is completely unpredictable.

Occasionally shivering is seen in one or both forelimbs. The gait is usually not affected; however, when the limb is picked up, the limb shows muscle tremors.

A recently recognized and poorly understood syndrome known as “stiff-horse syndrome” may resemble shivers. Affected horses have a stiff gait and muscle spasms in the epaxial muscles of the lower back and in the muscles of the hindlimbs. Spasms may be precipitated by voluntary movements or by someone picking up a limb. Increased levels of antibodies to glutamic acid decarboxylase have been reported.³¹

Abnormal flexion of one or both hindlimbs mimicking shivering has also been seen as a result of chorioretic mange affecting the distal aspect of the hindlimbs of a Shire horse.²³

Cause

Although an underlying neuropathy was proposed, careful study of two draft horses with shivers failed to reveal evidence of peripheral or central nervous system disease.¹ Examination of muscle from these and a small but growing number of horses with shivers of various breeds has revealed underlying EPSSM. Contiguous groups of glycogen-depleted skeletal muscle fibers in muscles of the proximal thigh and back have been seen in a small number of horses studied and indicate that this disorder may involve episodic muscle contracture (cramping).¹ However, a more recent study in Belgian draft horses failed to demonstrate a convincing association between EPSSM and shivers.³²

Biomechanical Basis

Explaining the abnormal gait of shivers is difficult. The possible role of episodic muscle cramp or abnormal

sensations within the affected leg is worthy of further study. Horses with an abscess in a hind hoof may show an abnormal flexing of the limb while standing that resembles shivers, and hind hoof abscesses often increase the abnormal action of the affected hindlimb in horses with shivers.

Medical Therapy

There is no reliable method of treatment. Change to a high-fat and low-starch and low-sugar diet may be beneficial in some horses after 4 to 6 months.^{2,8} Whether this therapy acts by decreasing muscle cramping, decreasing anxiety in the horse, a combination of these effects, or some other mechanism is still unknown. These horses include those in which muscle biopsy revealed characteristic changes of EPSSM and horses with no apparent abnormalities in the muscle samples examined. Improvement is often only partial, but most owners have been pleased with results, and it is conceivable that dietary therapy may help to slow the progression of the disease.

Surgical Therapy

No surgical therapy is available for shivers.

HINDLIMB EXTENSOR WEAKNESS

Group outbreaks of bilateral hindlimb extensor weakness resulting in knuckling of the hind fetlocks either transiently or for longer periods, or in horses with more severe signs, such as inability to ambulate faster than a walk or paraplegia, have been associated with the consumption of big bale silage or poor quality fungal-infested hay.³³ In some horses, clinical signs were mild and nonprogressive, whereas in others severe signs developed within hours. Affected horses showed no signs of flexor weakness or ataxia, but some showed proprioceptive deficits and reduced skin sensation. In some horses, spontaneous resolution of clinical signs was observed over 6 months, whereas in others clinical signs were slowly progressive. Post mortem examination revealed consistent evidence of neuronal degeneration in the sciatic nerves and to a lesser extent in the lumbar intumescence of the spinal cord; however, other peripheral nerves were not routinely examined. Clinical signs in some of the mildly affected horses were consistent with femoral nerve paralysis (see also Chapter 11).

Unilateral or bilateral femoral nerve paralysis most commonly occurs after general anesthesia.³⁴ If unilateral, the horse cannot extend the stifle and rests the limb in a flexed position on the dorsal aspect of the fetlock. If bilateral, the horse is unable to stand for any length of time, except in a crouched position with the hindlimbs flexed.

Intermittent knuckling of one or both hind fetlocks when ridden may be seen alone or in association with another cause of hindlimb lameness. It may reflect a proprioceptive deficit, altered limb placement in an attempt to minimize pain, or be neurologically mediated.²³ The rider may complain that the hindlimbs sporadically “give way.” Often young horses in early race training stumble or knuckle behind, a condition sometimes referred to as “loose stifles.” This condition may be more common in young Standardbred racehorses and is often managed with patellar intraligamentous or periligamentous injections of counterirritants. Efficacy is questionable, but in most horses the condition resolves as training continues.

STUMBLING

Stumbling may occur in front or behind. Stumbling in front is frequently a reflection of foot pain; foot placement is altered to try to minimize pain, resulting in a more “toe first” landing pattern. Stumbling behind may be a reflection of extensor weakness (see [Hindlimb Extensor Weakness](#) section). It may also be a reflection of hindlimb lameness that results in toe drag (see [Toe Drag](#) section). Stumbling either in front or behind is often worst on uneven footing.

FLEXION OF THE FETLOCK AND INABILITY TO LOAD THE HEEL

Permanent semiflexion of a fetlock with inability to fully load the heel may be the result of chronic desmopathy of the accessory ligament of the deep digital flexor tendon (DDFT). In forelimbs, this is usually unilateral and is the result of chronic work-related injury of both the accessory ligament of the DDFT and the superficial digital flexor tendon, with associated adhesion formation. In hindlimbs the condition may be unilateral or bilateral and is associated with a chronic degeneration of the accessory ligament of the DDFT (see Chapter 71).³⁵

TOE DRAG

Some clinically normal horses show a mild bilateral hindlimb toe drag, especially when worked on a soft surface, which may not be apparent under other circumstances.²³ A unilateral hindlimb toe drag is usually a reflection of a pain-related lameness. A bilateral hindlimb toe drag may reflect laziness, unfitness, long toes as a result of poor trimming, weakness, flexor weakness, bilateral lameness, ataxia, scirrhous cord, mastitis, and thoracolumbar or sacroiliac region pain.

PACING AT THE WALK

Walk is normally a four-beat gait: left hind, left fore, right hind, right fore. Occasionally a horse starts to pace at the walk, that is, the left hindlimb and left forelimb are advanced more or less simultaneously, followed by the right forelimb and hindlimb in an almost two-beat gait. This is often variable in degree within and between examinations and is usually most obvious when the horse is walking down an incline. This change in interlimb coordination is believed to be neurologically mediated, although no other gait abnormality or neurological deficit is detectable, and the mechanism has not been defined.³⁶ Other aspects of performance may be completely unaffected. The gait is not influenced by antiinflammatory analgesic drugs. The pace is considered a primitive gait, whereas the walk is one of the most complex because of the variability in overlap and lag time between limbs.³⁷ Once a horse has started to pace at the walk, it usually continues to do so. Pacing may have no clinical relevance in some horses, particularly older horses that curiously develop the condition spontaneously. However, in young horses not bred to pace (i.e., Standardbreds), pacing may be an early sign of progressive neurological disease.

STEPPING SHORT ON A HINDLIMB AT THE WALK

Stepping short on one hindlimb at the walk but with no detectable lameness at the trot is a poorly understood syndrome, which may be sudden in onset and tends to be persistent despite prolonged rest, with or without physiotherapy, osteopathy, chiropractic manipulation, or acupuncture treatment. Such horses have an obvious gait abnormality when ridden at the walk but perform normally at all other gaits. When examined moving in hand at the walk, the hindlimb gait is usually symmetrical. There is no response to antiinflammatory analgesic drugs or any local analgesic technique. Comprehensive radiographic, scintigraphic, and ultrasonographic examinations are unrewarding.

The gait may be influenced by neck position, being more obvious in a collected walk than if the horse is allowed to walk on a long rein. The cause is unknown. Continued work does not seem to have a deleterious effect.

UNUSUAL ABDUCTION OF A HINDLIMB

Rarely, a horse is observed to have excessive abduction of the hindlimb during protraction. Gait deficit is prominent at the walk but abates at the trot. No obvious source of pain can be found, and horses appear able to perform with this unusual gait deficit. Excessive abduction at the walk may be a manifestation of shivers, but we have observed this deficit rarely in light breeds as well.

OTHER MECHANICAL LAMENESSES

The biomechanical basis of mechanical lameness resulting in decreased flexion of the stifle and hock, such as fibrotic myopathy and upward fixation of the patella, is readily understood. These gaits are also characteristic and readily distinguished from other mechanical lamenesses. However, the mechanical lamenesses resulting in hyperflexion—that is, intermittent upward fixation of the patella, stringhalt, and shivers—have clinical similarities that can make them difficult to distinguish. One may also safely say that altered gaits from abnormal muscle or nerve function may not fall into one of the previously defined categories. A horse may appear stringy, locked up, have a goose waddle or stiff, stabbing hindlimb gait, or just appear off in a hindlimb because of mechanical lameness. A slight reduction in hock flexion at the walk may be considered normal for a horse, but this gait may also reflect a mechanical lameness (see Chapters 12 and 97).

In all horses with perplexing hindlimb lameness, the possibility of a form of mechanical lameness should be considered. This is especially true in breeds such as draft, Quarter Horse, and Warmblood-related breeds that are recognized to have a predilection for underlying myopathy. Because underlying myopathy or neuropathy is likely to be the most common cause of mechanical lameness, electromyography and muscle biopsy should be considered in all horses with mechanical lameness of the forelimbs or hindlimbs.

The Axial Skeleton

Chapter 49

Diagnosis and Management of Pelvic Fractures in the Thoroughbred Racehorse

Robert C. Pilsworth

Injuries to the pelvis of the horse have historically been considered uncommon.¹⁻³ They have also previously been described as invariably resulting from external trauma.⁴ Pelvic fractures are now recognized as a common cause of lameness in the racing Thoroughbred (TB). Stover et al⁵ confirmed a high incidence of stress fractures in the pelvis of American racing TBs examined at post mortem. Similarly in a clinical study performed in Newmarket, England, pelvic fractures were found to be common in the young racing TB.^{6,7} We now realize that pelvic fractures in the TB are most often the end stage of a cycle of bone fatigue and injury, commonly called stress-related bone injury. This has focused attention on early detection before the development of a full-blown displaced fracture. This section outlines steps to aid in early detection and management strategies subsequent to diagnosis.

PELVIC ANATOMY

The pelvis comprises the symmetrical halves and the sacrum in the midline. The left and right halves of the pelvis are joined in the ventral midline at the pubic symphysis. Although technically a joint, this becomes mineralized with age and is a bony union in most horses. A second joint occurs on each side between the pelvis and the head of the femur, forming the coxofemoral joint. The third joint is that between the ventral surface of the pelvis and the sacrum, the sacroiliac joint. Only the coxofemoral joint has any substantial degree of movement. The sacroiliac joint does have a synovial membrane, but it is largely immobile in many horses. In most horses the sacroiliac joint is spanned by dense bands of fibrous connective tissue, and despite having a cartilage surface, little or no movement takes place in the normal sacroiliac joint. Each half of the pelvis comprises three bones, which meet at the

acetabulum, the ilium cranially, the ischium caudally, and the pubis medially. The ilium has a large wing of bone extending from the tuber sacrale in the midline to the tuber coxae at the lateral extremity. The blade of the ilium narrows to form the shaft, which extends back to form the cranial segment of the coxofemoral joint. Caudal to the coxofemoral joint, and forming its caudal margin, is the ischium. Joining the two acetabula, forming the floor of the pelvis with its contralateral counterpart, is the pubis. The bones of the pelvis form a large fulcrum on which most of the gluteal muscle mass originates, to exert considerable propulsive forces on the hindlimbs. Although the pelvis can fracture anywhere as a result of external trauma or a fall, as is common with many other stress injuries, the forces involved in locomotion create predilection sites for stress fractures. These sites are associated with the concentration of forces involved in load bearing at speed and the biomechanics, innate structure, and form of the bone.

DIAGNOSTIC TECHNIQUES

Clinical Examination

A thorough working knowledge of the anatomy of the equine pelvis is essential for clinical examination to be useful. Because of the large muscle mass over the horse's hindquarters, only the bony extremities of the pelvis can be palpated. However, it is often possible to gain information about horses with pelvic injuries by studying the position of these bony landmarks. For example, the normal position and angle of the tuber coxae in the racehorse are often disturbed in horses with fracture or sacroiliac joint instability. The position of the tubera coxae can be assessed by viewing the horse from behind, with an assistant placing fingertips on the craniodorsal extremity of the tubera coxae (Figure 49-1). It is important that the horse stands completely level, with both hind feet together, for this test to be meaningful. Some horses, however, show asymmetry viewed in this way that is not linked to lameness. Similarly, careful palpation of the tubera sacrale can give information about the possible involvement of the sacral wing of the ilium or disruption of the sacroiliac joint.

Ventral displacement of one tuber sacrale is commonly encountered in ilial wing fractures, where the overlap of the fracture fragments seems to allow the tuber sacrale to move ventrally. Often a pain response is associated with palpation of a horse with tuber sacrale displacement, and sometimes movement of the bone itself may be felt if the fracture is complete. Fracture of a tuber coxae is often produced by external trauma, usually after a fall, but can also occur as a stress-related athletic injury. This usually results in a cranioventral displacement of the fracture fragment

Fig. 49-1 • Assessment of the position of the bony pelvis by fingertip levels placed on the dorsal extremity of the tubera coxae on either side.

because of the distractive forces of associated musculature. The tubera coxae in these horses can often be felt situated in the sublumbar fossa, and the remnant fracture bed can be palpated at the original site. Fractures of the ischium can sometimes be felt by manual palpation, although the extensive muscle spasm and protective boarding that are associated with these fractures often preclude this examination. Usually there is hemorrhage and swelling in the acute phase, but a clear loss of muscle mass or even a “hollow” in the caudal contour of the rump may develop with time as inflammation subsides. Finally, muscle tone in the tail and anus should be evaluated because fractures involving the sacrum can involve neural elements that supply these structures and cause flaccid paralysis of the tail, rectum, anal ring, and vulva (in a filly), that is, the cauda equina syndrome (Figure 49-2). Bilateral ilial wing fractures can produce the same neurological appearance associated with severe nerve root damage consequent on movement of the pelvis in relation to the sacrum.

Rectal examination allows direct manual assessment of the integrity of the pubis, internal surface of the wing of the ilium, and ventral border of the sacroiliac joint. Sometimes an obvious, sharp discontinuity in the bone surface can be felt, particularly in horses with fracture of the pubis. Gentle rocking of the horse by an assistant, while the clinician maintains digital contact with the bone surface of the pelvis per rectum, sometimes allows an appreciation of relative movement of adjacent bones or, more commonly, a sensation of crepitus. In horses with fracture of the ilial wing, a soft asymmetrical swelling can often be felt at the fracture site, representing a subfascial hematoma. The more serious and potentially fatal hemorrhage that occurs when an iliac artery is severed by the sharp dorsal edge of the fractured ilium often cannot be detected per rectum. If not immediately fatal, this free blood often percolates ventrally to cause massive swelling and edema of the thigh musculature.

Some horses have several stress fractures identified scintigraphically, only one of which may have initially collapsed, leading to overt lameness. Progressive collapse of the pelvis may then occur during the convalescent period, as incomplete fractures become complete and displaced because of bone resorption and weakening of the fracture

Fig. 49-2 • A horse with a sacral fracture. Note the abrupt angle change just behind the tubera sacrale, where the sacrum and coccyx have moved ventrally. The tail has complete flaccid paralysis. This filly had urine and fecal retention.

site. The degree of lameness seen in these horses varies enormously, depending on the type and extent of the fracture, and is considered separately in the following discussions of each class of fracture.

Diagnostic Ultrasonography

Ultrasonography is useful for diagnosing pelvic fractures and has proved especially useful in demonstrating fractures of the ilial wing (Figure 49-3), ilial shaft, tubera coxae, and ischium. Ultrasonography is quick, easy, and within the capability of clinicians with a suitable ultrasound machine. Ultrasonography may eliminate the requirement for a horse to travel to a referral center for diagnosis, and the risk associated with radiography under general anesthesia can be avoided. Ultrasonography has obvious limitations. For example, adequate imaging of the sacral wing, sacroiliac joint, and the femoral head is not possible. Fractures with minimal displacement or poorly developed callus are also difficult to image, as are incomplete fractures involving the ventral surface of the ilium. For this reason, ultrasonography should not be regarded as a standalone imaging modality for identifying a fracture of the pelvis but should be used with a thorough clinical examination and, if available, scintigraphy. In many horses, the exact site and extent of the fracture can be determined, which allow improved prognostic and management advice to be given. The healing process can be monitored by serial examinations, allowing the management program to be tailored to the individual horse (see Figure 49-3, B and C). A longitudinal- or sector-array ultrasound transducer can be used, provided it has a deep enough penetration to see the bone surface (i.e., a 3.5- or 5-MHz transducer). The muscle mass lying above the bone structures acts as a natural “standoff,” bringing the bone surfaces into the focal zone of the ultrasound beam. A separate standoff may be required to evaluate the position of the tubera sacrale and to detect any displacement. In thin-coated horses, no clipping is required,

Fig. 49-3 • A, Ultrasonographic image of the right ilial wing obtained using a 3- to 5-MHz transducer. There is a stress fracture of the ilial wing (*arrow*). The fracture appears as a discontinuity in the pelvis surface, with some comminution evident. Adjacent to the fracture is irregular echogenic material (callus), and just dorsal to the fracture is an anechogenic defect in the muscle (hemorrhage). Healing can be monitored by serial ultrasonographic examination, here at 63 days (**B**) and 109 days (**C**) following injury.

provided adequate saturation of the coat is achieved by degreasing with a detergent solution (chlorhexidine) or by soaking in surgical spirit, followed by application of a coupling gel before scanning. Horses with thicker hair coats must be clipped to obtain images of adequate quality. Images can be difficult to produce in horses with large amounts of subcutaneous fat because of the attenuating properties of this tissue. Numerous blood vessels running through the musculature can create acoustic shadows, which may be confused with a discontinuity of the bone surface. Identifying the bony landmarks such as the tubera sacrale, tubera coxae, cranial and caudal margins of the ilial wing, and greater trochanters of the femur allow anatomical orientation. A dry pelvic specimen is also useful in orientation. Both sides of the pelvis should be evaluated because the normal side can be used for comparison. However, keep in mind that bilateral ilial wing stress fractures occur and both sides may be abnormal. For recording and reference purposes, the area of the ilial wing imaged is referred to as line A, B, or C, and the distance from the tuber sacrale is measured. Scans aligned longitudinally along the ilial shaft are referred to as line D. This simple system is useful, especially in follow-up examinations. A systematic method for recording ultrasonographic findings has been published elsewhere.⁸

Radiography

Radiography of the pelvis is easily carried out in a foal when it can be performed under heavy sedation, for example, with a combination of detomidine and butorphanol, with the foal allowed to stand again shortly after the procedure. Standard projections include a ventrodorsal image with the foal lying on its back and a lateral image with the foal lying on its side on top of the cassette. A grid is mandatory to reduce scattered radiation produced by the large mass of soft tissue covering the pelvis. Radiography in adult horses is considerably more difficult. General anesthesia is required for thorough radiographic examination of the pelvis for numerous reasons, including the safety of the horse, personnel, and radiographic equipment. Administering general anesthesia to a horse suspected of having a pelvic fracture

is contraindicated because of the possibility of the horse displacing the fracture on recovery. Fracture displacement can lead to fatal hemorrhage or worsening of clinical signs, which is particularly true in horses with an incomplete fracture of the wing and shaft of the ilium. It is also difficult to get high-quality radiographs of the pelvic bones without extensive previous starvation of the horse to allow emptying of the gastrointestinal tract. Small, incomplete, pelvic stress fractures are extremely difficult to see radiologically. Three techniques for standing radiography in the horse have been described.⁹⁻¹¹ However, in my experience this has proved difficult, presents real risks of damage to the equipment, and is a substantial radiation hazard to attending personnel. The standing examination is also limited to examination of the acetabulum and ilial shaft, and images of the ilial wing are obscured by the sublumbar and overlying dorsal lumbar musculature. Image quality obtained in this way is also often poor; however, it may permit detection of substantially displaced fractures. Although radiography used to be the imaging technique of choice for assessing horses with pelvic fractures, it has been replaced by combined ultrasonographic and scintigraphic evaluation in many hospitals.

Scintigraphy

Scintigraphy is considered the most sensitive method of assessing acute bone damage in the horse (see Chapter 19).^{3,12-17} Special techniques for examining the pelvis have also been described, including an oblique image of the ilium, which is useful in diagnosing incomplete stress fractures in this site.¹⁶ Sacroiliac joint luxation has also been described as a scintigraphic diagnosis, the appearance of which is extremely similar to the ilial wing fractures observed by others.³ Equine scintigraphic techniques applicable to the pelvis, as well as numerous examples of normal and most types of pathology, have also been published in detail elsewhere.¹⁷ To examine the equine pelvis fully using a gamma camera, dorsal images of the entire pelvis are mandatory. The lateral image of the pelvis tends to be difficult to interpret because of the areas of focal greater radiopharmaceutical uptake (RU) observed at tubera coxae

and the coxofemoral joints in a normal horse. The massive muscle mass interposed between the slender bones of the ilial shaft and the gamma camera results in extensive shielding and poor images. Radioactive urine in the underlying bladder contributes to extensive background radiation, further decreasing image quality. Movement is a key factor in limiting image quality, but motion correction software can be used to minimize this complication. However, the lateral oblique image described by Hornof et al¹⁶ usually gives better images of the ilial wing and shaft. A caudal oblique image is also used by some to give better images of the coxofemoral joint and acetabulum. A method for scintigraphic examination of the pelvis using a hand-held probe has also been described.¹⁸ If a pelvic fracture is strongly suspected and initial scintigraphic examination is performed within 3 to 5 days of injury and is negative, a follow-up examination should be performed at least 10 days from the time of injury. Early fractures, even those with associated displacement, may not be evident scintigraphically for several days after injury.

FRACTURES OF THE TUBER COXAE

Fractures of a tuber coxae are often described as a knocked-down hip. They are relatively common and fairly straightforward to diagnose by clinical examination of the bony landmarks of the pelvis. They may occur after direct trauma or a fall but also as an athletic injury in training or racing.

Clinical Signs

On the first day of injury, the horse is moderately to severely lame, even at the walk. Often the horse shows intense muscle spasm and guarding of the affected hindquarter. The horse may sweat and scrape the ground, which can mimic signs of colic. The affected tuber coxae is often displaced cranioventrally and is palpable in the region of the sublumbar fossa. The parent bed from which the fragment originated is often palpable in the original site of the tuber coxae. Lameness rapidly resolves, and many horses are walking sound after only 24 to 48 hours, but they will still trot lame. Hemorrhage often occurs, which may present as a subcutaneous hematoma. Occasionally the sharp spiculated end of the ilium wears through the overlying skin, leading to development of an open fracture, which can be extremely difficult to treat because the skin overlying the sharp fragment will not heal and infection becomes a problem.

Radiographic Examination

A technique to evaluate the tubera coxae in the standing horse was recently described, but strict attention to limiting radiation exposure to attending personnel should be followed.¹¹ A medial 50° dorsal-lateroventral oblique radiographic image is obtained with the horse standing, sedated in stocks with the horse bearing weight on the affected limb and resting the unaffected limb, if possible.¹¹

Scintigraphic Examination

Scintigraphic examination is probably not indicated in most horses because the clinical diagnosis is straightforward. If performed, scintigraphic examination reveals

clinically significant focal increased radiopharmaceutical uptake (IRU) associated with the displaced tuber coxae and also a fairly obvious distortion of the normal anatomy of the pelvis on the dorsal image. In the Editors' experience, photopenic regions associated with ventral displacement of the fracture fragments may be present.

Ultrasonographic Examination

Directly after injury, horses with a tuber coxae fracture have clinical signs similar to those with other fractures of the pelvis, and an ultrasonographic examination helps to confirm the diagnosis and to define better the limits of the fracture. The fracture is easily seen as a disruption to the normally smooth and continuous contour of the ilial wing as it approaches the tuber coxae. A standoff may be required for better imaging of the bone immediately beneath the skin. It is important to perform a thorough examination of all the bony structures in case there are fractures in other regions of the pelvis.

FRACTURES OF THE ILIAL WING

Fractures of the ilial wing appear to be among the most commonly encountered type of athletic stress fractures in the skeletally immature TB racehorse.¹⁷⁻²⁰

Clinical Signs

A horse with a complete ilial wing fracture often shows lameness, but the initial lameness varies from lame at the walk to grade 1 to 4 of 5 at the trot. Lameness often resolves rapidly within 24 to 48 hours, and the horse then has a slight gait abnormality, walking with the back hunched up, but with no overt lameness. A horse with an ilial wing fracture often plaits with the hindlimbs at the trot and has a shortened stride. Although a complete fracture may be present on only one side, evidence of a subclinical stress fracture in the same site on the contralateral limb is common, and this may contribute to the peculiar gait shown by the horse. Obviously, pain from both sacroiliac joints considerably affects the freedom of movement of the hindlimbs. A horse with bilateral lesions may appear to have signs of exertional rhabdomyolysis, but plasma creatine kinase levels are often normal or only slightly increased (500 to 1500 IU/L).

Incomplete fractures may occur on one or both sides, and this can often show as poor propulsion and a poor hindlimb action rather than overt lameness. In a horse with a complete fracture, ventral displacement of the ipsilateral tuber sacrale is often apparent and can be detected by careful digital examination of the midline of the spine and both tubera sacrale. Firm pressure in the previous site of the tuber sacrale often evinces a marked pain response, with associated muscle spasm over the sacroiliac joint region. Palpating the tip of the tuber sacrale in its ventrally displaced position is sometimes possible. Often fairly profound muscle wastage is associated with this injury in the first 2 weeks, and this contributes substantially to the apparent asymmetry of the horse when viewed from behind. Bilateral complete fractures lead to profound stiffness, unwillingness to walk, and boarding of the muscles of the pelvis in response to digital manipulation. They can lead to collapse and inability to rise, with substantial neurological deficits in severe injuries.

Fig. 49-4 • A, Dorsal lateral oblique delayed (bone) phase scintigraphic image over the right side of the pelvis of a horse with a stress fracture of the ilial wing. Cranial is to the right. Focal increased radiopharmaceutical uptake (IRU) (arrow) appears about one fourth of the way between the tuber sacrale and tuber coxae, the most common predilection site for stress fractures of the ilial wing. Masking of areas of apparent greater RU, which are the consequence of normal bone with little attenuating soft tissue cover (tuber coxae), allows better recognition of the pathology otherwise obscured by “count capture” (**B**). (Courtesy Animal Health Trust, Newmarket, U.K.)

Scintigraphic Examination

Scintigraphy usually reveals marked focal IRU associated with the ilial wing, usually 10 to 15 cm from the midline (Figure 49-4). IRU may be bilateral or unilateral. A clear fracture line and the displacement of the ilial wing are sometimes visible. The lateral oblique image¹⁶ is particularly useful in determining whether the fracture extends to the cranial and caudal cortices of the ilial wing, although masking of the normal greater RU associated with the tubera coxae, caused by lack of attenuation of the gamma rays by overlying muscle as the bone approaches the skin surface, may be needed to highlight these changes (see Figure 49-4, B).

Ultrasonographic Examination

The normal ultrasonographic appearance of the ilial wing is a smooth and regular concave hyperechoic line, extending between the tuber sacrale and the ipsilateral tuber coxae. Acoustic shadowing and refraction artifacts can be created by the many blood vessels within the musculature and must not be confused with disruption to the bone contour. Ilial wing fractures appear as a disruption to the ilial wing contour, with changes ranging from a clear fracture gap to small irregular echogenic areas on the dorsal surface, representing prodromal periosteal new bone formation. The fractures normally run sagittally and involve the bone dorsal to or in proximity with the sacroiliac joint. The bone abnormalities often appear more severe toward the caudal margin of the fracture. Sometimes hemorrhage at the site of fracture appears as an anechoic defect in the normal heterogeneous echogenicity of skeletal muscle (see Figure 49-3, A).

FRACTURES OF THE ILIAL SHAFT

The ilial shaft is a common site for fracture after a fall or as a spontaneous athletically induced injury.

Clinical Signs

Fracture of the ilial shaft is extremely painful, producing non-weight-bearing lameness, and is often associated with shock from extreme pain and rapid blood loss. The tubera coxae often are markedly asymmetrical when viewed from behind, although encouraging the horse to bear weight equally to allow this examination to be carried out can be difficult. Sometimes with incomplete or minimally displaced fractures, no displacement of the tuber coxae is apparent initially, but in these horses the pelvis often collapses early in convalescence, at which time asymmetry becomes obvious. Collapse of the pelvis can often make the fracture less painful for the horse for reasons that are unclear. Rectal examination is often useful, and gentle rocking of the horse while the arm is inserted in the rectum often allows clear crepitus to be felt with the fingertips on the ilial shaft of the affected side. A hematoma next to the fractured ilium can also be easily palpated in many horses. Not uncommonly, horses damage the iliac arteries with the sharp edges of the comminuted fracture fragments, and this can result in severe and sometimes fatal hemorrhage.

Horses usually do not resent palpation and flexion of the distal aspect of the limb, although forced abduction of the limb, including the hock and stifle, may elicit a painful response. Palpation of the hindquarters usually results in intense muscle spasm and guarding on the affected side. Bizarre consequences of the severe lameness and change in functional anatomy after some of these fractures are not uncommon and include permanent upward fixation of the patella, contracture of the hamstring group of muscles, and spastic hyperextension of the tarsus. These complications invariably result in a grave prognosis.

Scintigraphic Examination

Many horses are too lame to allow transport to an equine clinic for scintigraphic examination, and a combination of clinical signs and ultrasonographic findings can establish

the diagnosis. If scintigraphy is performed, a caudal oblique image is often extremely useful in illustrating the extent and nature of the fracture. Because pelvic anatomy is directly visible on a scintigraphic image, the displacement of the fracture fragments and ilial wing is often easily appreciated.

Ultrasonographic Examination

The ilial shaft is examined by aligning the ultrasound beam in a craniocaudal direction and following the ilial shaft from the flat surface of the ilial wing toward the greater trochanter of the femur. With ultrasonography, a displaced ilial shaft fracture is easily detected as a discontinuity to the bone surface. Passive movement of the limb may show independent movement of the fracture margins in real-time scanning. Hypoechoic areas may be present around the fracture line and represent hemorrhage into the musculature. As with other fractures, if displacement is minimal, an ultrasonographic examination may fail to detect any pathological condition.

FRACTURES OF THE PUBIS AND ISCHIUM

Discrete fractures of the ischium are relatively uncommon. The horse usually has unilateral lameness with obvious swelling over the caudal aspect of the thigh. A fall or rearing over backward is often noted in the history, but these fractures can also develop as a spontaneous athletic injury. Often palpable crepitus and a marked pain response on firm digital pressure to the site are apparent. The tail may be held to one side because of muscle spasm associated with the painful lesion. Often focal sweating occurs on a patch of skin on the back of the thigh, presumably resulting from nerve damage. With time, the acute swelling subsides, and a “caved-in” appearance of the caudal aspect of the upper thigh may develop when viewed from the side.

Fractures of the pubis are uncommon and usually only encountered with other multiple pelvic fractures or after a fall.

Scintigraphic Examination

Scintigraphy shows focal IRU associated with the ischium and sometimes clear displacement of a segment of bone. Isolated fractures of the pubis can be difficult to see because of the mass of bone and muscle interposed between the fracture site and the gamma camera. For this reason, a hand-held probe, used per rectum, can give useful information. A bladder artifact produced by delayed excretion of urine may give the appearance of an IRU in this site.

Ultrasonographic Examination

The pubis is the least rewarding of the pelvic bones to examine by ultrasonography. A rectal probe is required, and only marked changes are detectable. The ultrasonographic examination is limited by the small degree of probe movement that is possible within the rectum, coupled with the irregular normal contour of the bone at this site.

Part of the ischium is also examined internally using a rectal transducer. This approach may be the only way to detect any ultrasonographic changes associated with an acetabular fracture. The caudal-most portion of the ischium and the ischiatic tuberosity can be examined percutaneously. Normally a smooth concave contour extends

caudally from the greater trochanter of the femur. Ultrasonographic changes similar to those described in other sites where bone damage has taken place can be seen in this area. Comparing the contralateral ischium with the fractured one is useful.

FRACTURES INVOLVING THE ACETABULUM

Horses with fractures of the ilial shaft and ischium that involve the acetabulum have the poorest prognosis of all for return to athletic function as a racehorse and normally develop osteoarthritis (OA) of the coxofemoral joint, which results in permanent and progressive lameness. Acetabular fractures commonly result from trauma, often subsequent to slipping over or being cast. This is one of the more frequent causes of lameness in a horse found not bearing weight on a hindlimb in the stable or paddock, with no obvious inciting cause.

Clinical Examination

The horse is extremely lame and is often unwilling to move. The horse has extremely short protraction of the hindlimbs at the walk and often hops rather than attempting to bear weight. Both Editors have observed that horses willing to walk with fractures or severe OA of the coxofemoral joint often have a shortened caudal phase of the stride, differentiating this area of pain from many others in the hindlimb. Pain occurs on abduction of the limb, and often firm palpation of the muscle mass around the coxofemoral joint causes muscle spasm and pain. Crepitus may be felt with displaced fractures if the hand is applied to the greater trochanter of the femur while the horse is walked, although commonly these fractures are incomplete and crepitus is not apparent. Crepitus may also be felt if the horse is rocked during rectal examination with the hand on the pelvic brim. In horses younger than 2 years of age, separation of the femoral head can occur from trauma and produces similar clinical signs to a comminuted acetabular fracture.

Scintigraphic Examination

Scintigraphic examination reveals focal IRU associated with the coxofemoral joint, greater trochanter of the femur, and ilial shaft on the affected side. The IRU is particularly visible on a caudal oblique image in which both coxofemoral joints can usually be seen using a large field of view gamma camera. OA of the coxofemoral joint contributes substantially to IRU in horses with a chronic fracture. These fractures are not associated with intense focal IRU initially, and early examination may give false-negative results. At least 1 week is required before scintigraphic abnormalities are detectable, and often this time period is necessary to allow humane transport of the horse. If the clinician is doubtful, the scan should be repeated 14 days later, when bone uptake will be maximal.¹⁶ Separation of the femoral head, which occurs infrequently in yearlings usually after a fall, produces similar scintigraphic changes, with moderate IRU associated with the coxofemoral joint.

Ultrasonographic Examination

Because of the great depth of the acetabulum and the many changing bone contours, the acetabulum is probably the most difficult area of the pelvis to image by

ultrasonography. Subtle pathological conditions may well be missed. The greater trochanter of the femur provides a good landmark by which to orient the image. The normal acetabular region is represented as a smooth and regular hyperechoic line of the acetabular rim. The greater trochanter of the femur is close to the skin surface as a hyperechoic line extending down and toward the acetabular rim. In some horses, a hypoechogenic region represents the joint space. In foals and immature animals, a hyperechoic convex line extends from the greater trochanter and represents the femoral head.

A fracture can appear as a discontinuity or irregular roughening of the acetabular rim and will be particularly obvious if greater degrees of callus are present.

PRINCIPLES OF TREATMENT OF HORSES WITH PELVIC FRACTURES

Surgical repair of pelvic fractures is not currently a realistic option in the adult horse. The period of box rest required for bony union ranges from 2 to 3 months, judged by monitoring fracture healing with ultrasonography. The end result in terms of the functional anatomy of the pelvis depends on the degree of displacement in the initial insult and the extent of subsequent distraction of the fracture fragments by subsequent muscle contracture. For example, tuber coxae fracture fragments heal by becoming adherent to the cranial wing of the pelvis through fibrous union. Despite the fact that the position of the tuber coxae often changes by several centimeters and the tuber coxae comes to rest in the sublumbar fossa, many horses make a full return to athletic function and race with success. Fractures of the sacral wing of the ilium are often nondisplaced and can make an extremely good, smooth bone union after healing (see [Figure 49-3](#)). Often an abnormal angle is apparent on the ilial surface because of distraction of the fragments by muscle contraction before healing. Although the abnormal angulation of the pelvic blade cannot help the stability of the sacroiliac joint immediately beneath the fracture, many affected horses go on to train and race successfully. In a review of 20 horses with ilial fractures, 15 horses made a full recovery to advanced race training, and 11 of these raced successfully.⁶ Involvement of the ilial shaft considerably worsens the prognosis for racing, although many heal adequately to allow retirement to stud. Some general principles of the care and management of horses apply equally to the different types of pelvic fractures and can be outlined as follows:

- Pain should be controlled during the initial phase by administration of nonsteroidal antiinflammatory drugs (NSAIDs), such as phenylbutazone, until the horse appears comfortable walking around the stable.
- The risk that normal recumbency in the box will result in displacement of an already fractured pelvis is always present. Unfortunately, the proximity of the sharp edge of the fractured ilium to the iliac arteries makes this a potentially life-threatening complication. Therefore a horse suspected of major pelvic bone injury should be tied up by the head during the initial convalescent period. When doing so, it is important that the horse has enough rope to move around comfortably, without a sufficient length to encourage it to attempt to lie

down. A “break string” should always be between the rope and the head collar, so that if a horse tries to lie down, it can do so without risk. Tying the horse in a position where it can see outside events is best, so that the horse is not alarmed by things happening behind it, to avoid the horse being startled and the risk of displacement of a lesion.

Horses should remain tied up for no more than 1 month. Many horses cope with being tied up without problems, but while they are tied up, horses should be fed from the floor several times a day and be held by an attendant while they eat. This encourages drainage of bronchial secretions from the trachea and may help to prevent pleuritis and pleuropneumonia, which can develop with prolonged periods of being tied up.²¹ During the period that NSAIDs are administered by mouth, any increase in rectal temperature will be masked. For this reason it is vital to take regular (every 48 hours) blood samples to assess changes in white blood cell count, serum amyloid protein A (SAA), and fibrinogen level, which may signal an early onset of pneumonia or pleuritis. Subsequent to NSAID therapy, rectal temperature should be monitored twice daily. When a horse is untied after 1 month, the fracture fragments possibly still can displace, leading to fatal hemorrhage. However, displacement is rare, and the clinician must balance the potential risk to the horse against the humanitarian aspects of keeping a horse tied up continuously for more than 1 month. Although I feel strongly about tying up horses with pelvic fractures, others feel differently, and many horses with pelvic fractures have been managed successfully without being tied up.

- Once untied, a horse requires a minimum of another 1 to 2 months of stable rest, depending on the extent and severity of the fracture, combined with daily walking exercise to encourage normal blood flow to the feet, before turnout is safe. Pasture rest for another 2 months is then advisable for horses with a severe, displaced fracture, even before contemplating covering. Pregnancy and parturition can severely test fracture healing; therefore a prolonged convalescent period is required. Often questions arise about the suitability of mares undergoing pregnancy and parturition after pelvic fractures. In my experience, the main concerns are lameness, the ability to get up and down, and maintaining weight rather than callus formation and the physical inability to deliver a foal.
- If a pelvic fracture has led to an extreme unilateral lameness, the contralateral foot is at real risk of developing laminitis. Many horses will not allow the contralateral limb to be raised long enough to fit a frog support. Therefore it is vital that the horse is bedded on deep litter (bedding), so that the bedding can pack up under the foot to give some support. A frog support should be placed as soon as possible, and the shoes should be removed. Once the horse is able to bear weight on the affected limb, short periods of walking exercise help prevent vascular stasis and lymphangitis that often accompany weight bearing on one limb for prolonged periods. Walking may also help prevent supporting limb laminitis, but only if the horse is not profoundly lame in the affected limb. Support bandaging of the

contralateral limb in horses with severe unilateral lameness is probably worthwhile and certainly helps to prevent the occurrence of lymphedema.

- Administration of acetylpromazine in small doses (25 to 50 mg orally twice daily or 0.02 to 0.04 mg/kg injected intramuscularly twice daily, judged on degree of tranquilization by the first dose) to a lame horse helps for three reasons: preventing laminitis (although the evidence for efficacy is limited; see Chapter 34); relieving some anxiety and allowing the horse to rest, which is important for recovery; and preventing upward fixation of the patella, to which the horses are prone, presumably by causing mild muscle relaxation.
- Most horses with incomplete or minimally displaced complete ilial wing stress fractures become sound rapidly. I do not normally keep these horses tied up, but nonetheless a small but real risk of fatal hemorrhage exists in these horses, even when they are apparently sound. Displacement is rare, but from the outset the risk should be explained to and understood by all involved in the management decisions. These horses will often commence walking exercise much more quickly (after 2 to 4 weeks) and return to trotting at 6 weeks, with a rehabilitation period of 8 weeks.
- Adult horses with fractures involving the acetabulum have the poorest prognosis for return to athletic function, although horses often become sound enough to be retired to pasture. Compromise of the diameter of the pelvic canal can be a complication, especially if the ilial shaft is involved and the fracture has healed with abundant callus. Even for experienced clinicians, being categorical about the ability of a mare with a narrowed pelvic canal to breed can be difficult. Often a trial mating to an inexpensive stallion is the most

pragmatic management choice, if the clinician has doubts.

Careful thought should be given to each individual horse to make sure that the horse's future is worthwhile, in terms of quality of life for the horse and the economic realities of the situation, before subjecting a horse to a prolonged and, by necessity, painful convalescent period.

Prognosis in foals with acetabular fractures is considerably better than in adult horses. Treating a foal with an acetabular fracture is definitely worthwhile because at this age the pelvis appears capable of healing with much less chance of the development of OA in the coxofemoral joint when compared with adult horses. Foals are treated with 12 weeks of box rest initially and progressive turnout in a nursery paddock.

Separation of the femoral head in a young horse carries a hopeless prognosis and, if confirmed, should lead to immediate euthanasia.

- As with any horse that has had a prolonged period of box rest, the clinician must remember that although the pelvic fracture may have healed, the rest of the horse's skeleton will have demineralized substantially because of disuse. Therefore it is vital that horses are treated as "naïve skeletal specimens" when training is resumed. The exercise program should increase gradually, beginning with walking only for the first 2 weeks and building up gradually through walking and trotting to slow speed cantering, eventually reattaining race speed training. Clinicians should remember that the skeleton takes approximately 1 month at each gait to adapt to the loads placed on it. Bringing a horse back from injury often takes as long as the period of box rest itself, if further orthopedic problems are to be avoided.

Chapter 50

Lumbosacral and Pelvic Injuries in Sports and Pleasure Horses

Sue J. Dyson

ANATOMICAL CONSIDERATIONS

Detailed anatomy of the ilium, ischium, pubis, sacrum, coxofemoral joint, sacroiliac joints, nerves, and major vessels is described elsewhere (see Chapters 49, page 564, and 51, page 583). The lumbosacral joint comprises five separate joints: the intercentral joint between the caudal aspect of the vertebral body of the sixth lumbar vertebra and the sacrum, between which is an intervertebral disk; two intertransverse joints; and two synovial intervertebral articulations between the articular processes of the sixth

lumbar vertebra and the cranial articular processes of the sacrum. Movement is principally restricted to flexion and extension because of the large transverse processes.¹ Congenital variations in anatomy can be seen, including fusion of the fifth and sixth lumbar vertebrae or sacralization of the sixth lumbar vertebra resulting in lumbosacral ankylosis. These result in stress concentration on adjacent joints. The biomechanical stresses of movement of the lumbosacral joint place particular compression and traction forces on the intervertebral disk, which may predispose to disk degeneration.

CLINICAL SIGNS

History

Pelvic injury in a mature athletic horse is a comparatively unusual cause of lameness, except as the result of trauma from a fall, rearing and falling over backward, becoming cast in the stable, or sustaining an injury during transport. When the horse has no history of trauma, diagnosis can be difficult, and excluding all possible sources of pain in the distal aspect of the limb is frequently necessary before focusing on the pelvic region.

Horses with clinically significant pathological conditions of the lumbosacral or sacroiliac joints frequently have a history of progressive reduction in performance, difficulty engaging the hindlimbs, and poor hindlimb impulsion, especially when ridden.^{2,3}

Clinical Examination

Clinical assessment of individual structures of the pelvic region by visual examination and palpation is not easy, especially in Warmblood and draft breeds, because of the large muscle mass of the hindquarters. Frequently, only the tubera coxae and tubera sacrale can be palpated. Large muscle mass may prohibit palpation of the greater trochanter of the femur. Atrophy of the hindquarter musculature is nonspecific and can reflect disuse because of pain arising anywhere in the limb, although atrophy of the muscles around the tail head often reflects injury to the tuber ischium or local nerve damage. Asymmetry of the height of the tubera sacrale is a common finding in horses in full work, free from lameness, although it may be seen along with poor performance or alterations in hindlimb gait. Apparent asymmetry may actually reflect differences in size of the dorsal sacroiliac ligaments. Alteration in muscle mass in the proximity of the tubera sacrale superficially can give a false impression of asymmetry of the tubera sacrale. Asymmetry of the tubera coxae may reflect a previous injury unassociated with ongoing pain. Poor muscle development in the lumbar region and over the hindquarters may make the tubera sacrale and the summits of the dorsal spinous processes of the lumbar vertebrae appear abnormally prominent. This should alert the clinician to the possibility of thoracolumbar or pelvic pain; however, this finding is nonspecific and may reflect the horse's work history.

The pelvic region should be appraised visually and palpated systematically, and although preliminary assessment is usually best performed in the stable, for accurate evaluation of symmetry of the musculature and bony elements of the pelvic region the horse should be standing completely squarely behind on a firm, level surface with the horse looking straight ahead. In a horse with severe lameness this may not be possible because the horse may be unwilling to load the lame limb fully. Careful differentiation should be made between muscular and bony asymmetry. Muscle atrophy can make accurate assessment of symmetry of the pelvic bones difficult. To evaluate accurately the levelness of the tubera coxae, two assistants each must place an index finger on the craniodorsal aspect of each tuber coxae and extend the finger horizontally, or the tubera coxae should be marked using tape. Elevation of the tail may be necessary to identify muscle atrophy around the tail head, which may be seen along with nerve damage, or injuries of the ipsilateral tuber ischium.

Assessment of symmetry when the horse is unwilling to bear weight evenly on both hindlimbs is not easy, but particular attention should be paid to the way in which the limb is positioned. An abnormally straight limb may reflect luxation of the coxofemoral joint and secondary upward fixation of the patella. The greater trochanter of the femur of the lame limb may appear higher than that of the contralateral limb.

The muscles of the lumbar and pelvic regions should be assessed carefully to identify any area of abnormal

muscle tension, pain on palpation, or unusual firmness. Firm stroking of the muscles first with a finger and then with a blunt-ended object (e.g., artery forceps) is useful to determine whether muscle spasm or muscle fasciculation is induced. Palpation of the caudal muscles of the thigh is also important because abnormal pain or tension can reflect primary muscle injury or an injury of the ipsilateral tuber ischium.

Firm pressure should be applied to the bony prominences to see whether pain or an abnormal reaction, such as sinking on the hindlimbs when pressure is applied to the tubera sacrale, can be induced. Both tubera coxae should be grasped simultaneously and the horse rocked from side to side to determine whether crepitus can be detected by palpation or auscultation, bearing in mind that the absence of crepitus does not preclude a fracture. Pull the tail while holding one hand over the coxofemoral joint; palpable crepitus may reflect a fracture, severe osteoarthritis (OA), or subluxation of the joint.

Careful, systematic examination of the pelvic canal region per rectum is also indicated to assess the aorta and iliac arteries, psoas musculature, the lumbosacral joint, the caudal aspect of the ilial shaft, and the pubis and ischium.

Pelvic injuries should also be considered when a clinician examines a recumbent horse that has fallen over a fence. Palpation of the pelvic region is even more difficult in these circumstances. Even with a severe fracture, palpating any abnormality may be impossible. The clinician should bear in mind that in the acute phase, local reflexes such as the patellar reflex and the withdrawal reflex may be suppressed, which does not necessarily reflect a spinal cord injury. Major fractures may be associated with rupture of one or more large vessels, resulting in potentially fatal internal hemorrhage. Thus it is important to assess the recumbent horse as a whole, monitoring pulse rate, color of mucous membranes, and capillary refill time. Increased pulse rate and progressive pallor of the mucous membranes are good indicators of major vessel rupture, such as laceration of the iliac artery after fracture of the ilial shaft.

Manipulation of the limb may be resented if pain is associated with the coxofemoral joint, but generally the responses to flexion of the limb, protraction, retraction, and abduction are rather nonspecific. A horse with pain associated with the sacroiliac joints or a coxofemoral joint may be reluctant to stand on one limb, with the other limb raised, and may behave awkwardly in anticipation of discomfort. However, the reaction is nonspecific, and one must bear in mind that some horses present difficulties in picking up the hindlimbs in the absence of any sign of lameness or poor performance. Difficulties in picking up hindlimbs may be caused by reluctance to accentuate weight bearing on the lamest limb, reluctance to flex the lame limb, or may be psychological. If the horse is a shiverer, unilaterally or bilaterally, the response to hindlimb flexion can be difficult to assess.

The degree and character of lameness depend on the underlying cause. Fracture or luxation of the coxofemoral joint results in acute-onset severe lameness. Lameness associated with other lesions in the pelvic region may vary in degree, not only among horses with similar lesions but also within and between examination periods. Pain from the coxofemoral joint frequently results in the horse moving on three tracks, with the nonlame limb being placed

between the two forelimbs. On the lunge the horse may be inclined to break to canter rather than move with adequate hindlimb impulsion, but this is not specific for pelvic pain and is typical of many horses with hindlimb lameness. Pain associated with the coxofemoral joint or the greater trochanter of the femur sometimes results in the horse carrying the lame limb in canter. Lesions associated with the sacroiliac joints frequently result in the horse crossing over each hindlimb at the trot (i.e., plaiting), but this is not pathognomonic, and some horses move with a base-wide hindlimb gait.² The horse may move with reduced hindlimb impulsion rather than overt lameness. Although acute fractures of the tuber ischium invariably cause lameness, chronic injuries may result in loss of performance (e.g., jumping to the right) rather than overt lameness.

The response to flexion tests is nonspecific. The clinician should bear in mind that increased weight bearing on one limb, caused by flexing the contralateral limb, may accentuate lameness in the weight-bearing limb. Turning the horse in small circles, inducing rotational forces on the coxofemoral joint, may accentuate lameness associated with the coxofemoral joint.

Ridden exercise is invaluable in horses with a history of poor performance, reduced hindlimb impulsion, or low-grade lameness because frequently the lameness or restriction in hindlimb gait is accentuated. This may be most obvious in deep footing. Some horses with sacroiliac joint region pain or lumbosacral region pain show extreme reluctance to go forward freely. Affected horses may feel to the rider much worse than they appear to a trained observer. However, care must be taken to differentiate these horses from those with bilateral hindlimb lameness, thoracolumbar pain, or recurrent low-grade exertional rhabdomyolysis and those performing poorly because of the rider (see Chapter 97), previous poor schooling, or a combination of boredom and an unwilling temperament.

Analgesic Techniques

In horses with chronic lameness, reduced hindlimb impulsion, or poor performance, excluding the distal aspect of the limb as a source of pain by performing perineural analgesia of the fibular and tibial nerves and intraarticular analgesia of the three compartments of the stifle joint may first be necessary. If the response is negative, intraarticular analgesia of the coxofemoral joint may be indicated. This is relatively straightforward to perform if the horse is not well muscled and the greater trochanter of the femur is readily palpable. However, in the majority of heavily muscled, mature competition horses, needle placement must be guided by ultrasonography.⁴ Even if the needle is accurately positioned, retrieval of synovial fluid may be difficult. Extraarticular deposition of local anesthetic solution may result in transient paralysis of the obturator nerve and instability of the limb. The technique is described in Chapter 10.

Intraarticular injection of the sacroiliac joint cannot be achieved; however, infiltration of local anesthetic solution around the sacroiliac joint region may result in dramatic clinical improvement, presumably by alleviation of pain associated with the joint and periarticular structures. It cannot be considered an entirely specific technique and potentially could also influence pain from the lumbosacral joint and local nerve roots. The techniques are described

on page 589. Infiltration of local anesthetic solution around the sacroiliac joint regions resulted in significant improvement in 95 of 108 horses with clinical signs suggestive of sacroiliac joint pain.⁵ Horses were reassessed ridden 15 minutes after injection. If local anesthetic solution is placed too far caudally there is the possibility of inducing sciatic nerve paralysis either unilaterally or bilaterally. In my experience, this is extremely rare (<2%), but if bilateral, the horse will become recumbent and may remain so for up to 3 hours before returning to normality.⁵

Serum Muscle Enzyme Concentration

Measuring serum concentration of creatine kinase (CK) and aspartate transaminase (AST) is invaluable for diagnosing horses with acute and chronic rhabdomyolysis (tying up). In horses with chronic tying up, comparing resting levels with concentrations reached after maximum exercise may be necessary. Peak levels of CK are likely to occur 3 hours after exercise. If a horse has had a tying-up episode within the past 4 or 5 days, AST levels almost invariably will be increased. Some horses with chronic recurrent problems have constantly elevated levels of CK and AST. The degree of elevation of muscle enzyme concentrations may show a poor correlation with the severity of clinical signs.

DIAGNOSTIC IMAGING

Radiography

Radiographic examination of the pelvic region of a horse, anesthetized and positioned in dorsal recumbency or in the standing position, is described in depth elsewhere.⁶ Since the advent of nuclear scintigraphy and diagnostic ultrasonography the indications for radiographic examination have decreased. If the source of pain has been localized to the coxofemoral joint, radiographic examination is indicated to determine the nature of the pathological condition and hence prognosis. High-quality radiographs can only be obtained with the horse positioned in dorsal recumbency under general anesthesia. Evaluation of the sacroiliac joints can be difficult because of the superimposition of abdominal viscera. Identification of new bone formation on the caudal aspect of the joint and irregular joint space width are poor prognostic indicators. Nuclear scintigraphic examination gives accurate information about bone turnover, but anatomical detail is less well defined. Therefore radiography of a horse with a suspected acetabular fracture may be indicated at least 6 weeks after the onset of lameness to determine whether a suspected fracture involves the coxofemoral joint, which merits an extremely guarded prognosis for return to full athletic function in a mature horse.

Radiographs of the coxofemoral joint, caudal aspect of the ilial shaft, and the ischium obtained in the standing position may be satisfactory for confirmation of luxation or major fractures of the joint.⁶ A dorsal 50° proximal medial–ventrodorsal lateral oblique image can be used to assess the integrity of the tubera coxae in a standing horse.⁷

Ultrasonography

Diagnostic ultrasonography of the pelvic region can be performed transcutaneously or per rectum.^{8,9} The choice of transducer frequency depends on the structures to be

imaged. Transcutaneous evaluation of the bony elements of the pelvis and the deep musculature requires a 5- or 3.5-MHz transducer, depending on the size of the horse, whereas evaluation of the dorsal sacroiliac ligaments, sublumbar musculature, ventral aspect of the lumbar and sacral vertebrae, and aorta and iliac arteries is better performed using a 5- or 10-MHz transducer. Evaluation of nerve roots per rectum may be best achieved using a 10- to 12-MHz transducer.

Diagnostic ultrasonography is useful in evaluating fractures (see Chapter 49, page 564), assessing muscles (see Chapter 83) and the sacroiliac ligaments (see page 578), determining blood vessel patency (see page 581), assessing the lumbar vertebrae and articulations, and evaluating nerve roots.

Nuclear Scintigraphy

Nuclear scintigraphic evaluation of the pelvic region is useful for identifying fractures, stress reactions in bone, increased bone modeling associated with OA and other bony lesions, and evidence of rhabdomyolysis; for evaluating blood flow in the aorta, iliac, and femoral arteries; and for assessing the sacroiliac joints.¹⁰ Sensitivity of the technique in part depends on the angle of the gamma camera to the area of interest and the degree of overlying muscle mass. It is important to recognize that some lesions may be bilateral; therefore recognition of the normal scintigraphic appearance of the region in horses of different ages and different disciplines is important. The clinician should bear in mind that superficial bony structures such as the tubera coxae and tubera sacrale always have apparently greater radiopharmaceutical uptake (RU) than deeper structures. Unilateral muscle atrophy and shape of the pelvis may also confound interpretation.¹⁰⁻¹⁴

Radioactive urine in the bladder may complicate interpretation; therefore the judicious use of furosemide to induce urination before examination is essential.

Complete evaluation of the pelvic region requires dorsal images of the sacroiliac joints, oblique images of the ilial wings, caudodorsal and caudal images of the tubera ischii, and lateral and caudolateral images of the coxofemoral joints. Care must be taken in interpreting the appearance of the sacroiliac joints because age-related changes occur in normal horses.¹⁰⁻¹⁵ Swaying movement of the horse during image acquisition can result in images that mimic abnormalities, and using motion correction software is invaluable.

DIFFERENTIAL DIAGNOSIS

Fractures

Clinical features, diagnosis, and treatment of fractures of the pelvis in the young Thoroughbred (TB) racehorse have been dealt with in depth (see Chapter 49), and this section focuses on differences in mature athletic horses. The incidence of stress or fatigue fractures of the pelvic region in the mature horse is low, except in horses that race over fences, which have a substantial incidence of ilial stress fractures. The clinical features are similar to those in the young racehorse (see Chapter 49), although there is a higher prevalence of horses with fractures extending into the ilial shaft that have a guarded prognosis. The majority of other fractures result from external trauma.

Tuber Ischium

Trauma to or fractures of the tubera ischii sometimes occur in event horses that fall when jumping up onto a bank, may also occur in any horses as a result of a fall on the flat, and also have been recognized in horses from other disciplines with no known history of trauma.¹⁷⁻¹⁹ Lameness is usually acute in onset and severe. Mild localized swelling is easily overlooked unless the tuber ischium is suspected as a site of injury. The ipsilateral semimembranosus and semitendinosus muscles are usually sore to palpation. Atrophy of the muscles around the tail head often develops within 7 to 10 days. Usually crepitus is not palpable. In horses with chronic lameness, pain on palpation may not be evident, although the tubera ischii may appear asymmetrical, and the lameness may be only mild or moderate.

Diagnosis of a fracture of the tuber ischium can be confirmed using nuclear scintigraphy (Figure 50-1). Dorsal oblique and caudal images are useful. Usually increased radiopharmaceutical uptake (IRU) and an abnormal pattern of uptake are apparent.¹⁶ In some horses determining whether the fracture is complete and whether it has become substantially displaced may be possible. It is important to recognize that IRU may persist for many years after injury, and therefore the results of scintigraphic examination must be carefully correlated with the results of clinical examination.¹⁹ Discontinuity of the bone outline may also be confirmed using diagnostic ultrasonography. Limited radiographic examination can be performed in a standing horse, but it is most easily and safely done with the horse under general anesthesia. Less commonly there is enthesseous reaction with IRU in both the tuber ischium and the ipsilateral semimembranosus and/or semitendinosus muscles. Ultrasonographic examination may demonstrate irregularity of the tuber ischium and decreased or increased echogenicity of the injured muscles depending on the acuteness or chronicity of injury.

Treatment by restriction to box rest usually results in a satisfactory outcome, although occasionally sequestration

Fig. 50-1 • Caudal scintigraphic image of a 7-year-old part Shire riding horse with acute-onset left hindlimb lameness after falling over while being shod. There was no response to tibial and fibular nerve blocks or to intraarticular analgesia of all three compartments of the stifle joint. There is an abnormal pattern of radiopharmaceutical uptake and increased radiopharmaceutical uptake in the left tuber ischium consistent with a displaced fracture of the tuber ischium, which was confirmed using ultrasonography.

of the fracture fragment occurs, necessitating surgical removal.

Occasionally a horse shows no obvious lameness, but it has reduced performance and a tendency to jump drifting consistently to one side because of pushing off unevenly with each hindlimb. This symptom is associated with reduced muscle development over one of the tubera and IRU in the tuber ischium (see Figure 12-4). The outline of the tuber ischium appears irregular in an ultrasonographic image.

Iliac Wing and/or Shaft

Fractures of the iliac wing and/or shaft are unusual in mature sports horses and are almost invariably the result of a heavy fall when jumping and may be catastrophic if the fracture(s) becomes displaced and results in laceration of the iliac artery and fatal hemorrhage. Initial diagnosis is challenging because the horse is invariably recumbent and may mimic a severely winded horse, which may remain down for 30 to 45 minutes. There may be remarkably few signs of pain considering the severity of injury. If the horse is in lateral recumbency with the affected limb down, the horse may be unable to make any attempt to get up. Examination per rectum may facilitate a diagnosis. In my experience, most of such fractures have been fatal. Monitoring pulse and respiratory rates and color of the mucous membranes is the best method of diagnosing potentially fatal hemorrhage.

Tuber Coxae

Fractures of a tuber coxae in sports and pleasure horses have little difference to those in racehorses (see Chapter 49). The prognosis is usually favorable, with 27 of 29 horses (93%) returning to full athletic function.⁷ Horses with partial fractures of the cranial or caudolateral aspects of a tuber coxae returned to use more quickly than horses with complete transverse, longitudinal, or oblique fractures (mean 3 months vs. 6.5 months).

Greater Trochanter of the Femur

Fracture of the greater trochanter of the femur is an unusual injury causing severe lameness. The fracture fragment is often displaced cranially because of the pull of the attachments of the deep and middle gluteal muscles.

Usually no localizing clinical signs are apparent unless the horse is poorly muscled and the greater trochanter is readily palpable. The diagnosis is based on nuclear scintigraphic examination, with or without diagnostic ultrasonography. The prognosis for return to athletic function with conservative treatment is guarded.

Sacrum

Fractures of the sacrum may be complete or incomplete and result in bilateral hindlimb lameness. If the fracture is complete, the contour of the hindquarters when viewed from the side changes, so that the rump has abnormal angulation (Figure 50-2). Associated neurological signs include flaccid paralysis of the tail, reduced sensation around the tail head, urine dribbling in a mare, and loss of anal tone. The onset of neurological signs may be delayed for several weeks after the primary fracture. The fracture may be palpable per rectum. The fracture may be confirmed radiologically and using diagnostic ultrasonography per

Fig. 50-2 • Dorsal bone phase scintigraphic image of the pelvic region of a 12-year-old Thoroughbred mare, a former winner of the European Three Day Event Championships. The mare had shown slight but clinically significant loss of performance with no overt lameness. She had never shown any signs typical of classical tying up. There are linear stripes of abnormal radiopharmaceutical uptake in the gluteal muscles, which also were seen in the psoas, biceps femoris, and semitendinosus and semimembranosus muscles. This is compatible with recurrent exertional rhabdomyolysis and was associated with persistently elevated levels of creatine kinase and aspartate transaminase.

rectum. The prognosis for return to athletic function is guarded, although horses with more caudal fractures have made a complete functional recovery. Fractures of the femur are considered in Chapter 47.

Equine Rhabdomyolysis (Tying Up)

Equine rhabdomyolysis is considered in depth elsewhere (see Chapter 83). This section focuses on aspects of diagnosis and differential diagnosis of lameness associated with the hindquarters and pelvic injuries in sports horses used for different disciplines and is restricted to recurrent exertional rhabdomyolysis (RER).

The spectrum of clinical signs associated with RER is enormous. A horse may have mild bilateral hindlimb stiffness or loss of freedom of action that may deteriorate slightly with work, without the horse becoming unduly distressed, but the horse sometimes requires a prolonged recovery period after work. Such horses may have no palpable firmness of the hindquarter musculature or pain induced by firm palpation and a normal pattern of sweating. The horse may be able to compete but performs below expectations. These clinical signs are not unique to exertional rhabdomyolysis and may be seen in horses with severe thoracolumbar discomfort associated with impinging dorsal spinous processes, pain associated with the sacroiliac joints, or bilateral hindlimb lameness. Some horses show progressive agitation during ridden exercise and awkwardness to ride, without recognition of a gait abnormality. Careful clinical evaluation usually reveals a progressive shortening of stride.

Alternatively, a horse may start to jump poorly during, for example, the cross-country phase of a Three Day Event and pull up with a unilateral hindlimb lameness, with no localizing clinical signs, that resolves within 24 hours. In

contrast, a different horse may have recurrent acute-onset, severe episodes—often provoked by competition, for example, during the cross-country phase of a Three Day Event—that may be so bad as to result in recumbency. An endurance horse may demonstrate unilateral or bilateral hindlimb lameness at the final vet gate but show no typical signs of tying up.

The incidence of RER depends to some extent on the discipline in which the horse is involved, occurring most commonly in racehorses (see Chapters 83, 106, and 107), endurance horses (see Chapter 118), and event horses (see Chapter 117). RER is unusual in show jumpers and dressage horses but occasionally occurs in competitive TB-type ponies. In all these horses, the results of muscle biopsies usually indicate no evidence of abnormal glycogen metabolism as in polysaccharide storage myopathy, which occurs more commonly in draft and draft crossbreeds and Quarter Horses. In the TB, evidence indicates that RER may be a heritable condition, as an autosomal recessive trait with variable expression.²⁰ A familial trait has also been observed in some part-TB event horses. However, RER in many event and endurance horses does not become apparent until the horse is middle aged, or even older. The condition is manifest more frequently in mares than in stallions or geldings.

Diagnosis is based on measuring elevated serum muscle enzymes (CK and AST) after exercise (see page 573). The degree of muscle enzyme elevation frequently does not correlate with the severity of clinical signs. Interpretation is not always straightforward because asymptomatic endurance horses frequently have extremely high levels of CK and AST during and after a ride. Horses with low-grade RER, which occurs daily, often have constantly elevated levels of CK and AST, even if rested.

Nuclear scintigraphy can be useful in horses with low-grade hindlimb stiffness and poor performance to validate a diagnosis of suspected RER,^{10,21} to evaluate blood flow to the hindlimb musculature,²² and to exclude any other concurrent musculoskeletal lesions. In association with RER in some but not all horses, abnormal uptake of ^{99m}Tc-methylene diphosphonate occurs in the affected muscles in the bone phase of the scan, appearing usually as linear streaking (see Figure 50-2), but in horses with more severe, long-standing RER, affected muscles may show large areas of intense IRU. Lesions are not restricted to the gluteal muscle mass, but they may also affect quadriceps, biceps femoris, semitendinosus, semimembranosus, psoas, and longissimus dorsi muscles. Lesions may be symmetrical or asymmetrical. However, normal RU does not exclude RER.

Muscle biopsy is used to determine whether any evidence exists of polysaccharide storage myopathy. Feeding horses a high-fat and low-carbohydrate diet may reduce the frequency and severity of attacks after a period of 3 to 6 months.²³

Measuring fractional excretion of electrolytes (sodium, potassium, calcium phosphorus, and chloride) can be useful to identify those horses that seem unable to absorb or to use normally specific dietary electrolytes and that might benefit from dietary supplementation.^{24,25} For accurate interpretation of results, it is important that the horse is consuming its normal diet and has recovered from any recent acute attack of exertional rhabdomyolysis when blood and urine samples are collected. A midstream urine sample should be collected, preferably freely voided rather

than by catheterization. Results are only valid if serum creatinine is within the normal range and the fractional excretion of creatinine is normal. Results should be compared with the normal ranges for a horse on a similar diet because results for horses eating an oat- and hay-based diet are different than for those on a cube-based diet or a diet high in alfalfa. Fractional excretion ratios for potassium tend to be high if the horse is allowed access to pasture. Low values for fractional excretion ratios for sodium or calcium indicate that the diet should be supplemented with sodium chloride or either calcium carbonate or calcium gluconate, respectively. Appropriate dietary supplementation may help to prevent further attacks.

Management practices may also help to prevent attacks in some horses. These include daily work, with a long, slow warm-up period, turnout as much as possible, and avoiding undue stress, especially in highly strung, nervous individuals. However, some horses, especially those with daily low-grade clinical signs that are not stress provoked, prove intractable to successful management.

Muscle Injury

Muscle soreness is frequently unassociated with any recognizable histopathological changes within the muscle and is often secondary to some other cause of lameness because of the altered way in which the horse is moving. Muscle soreness can often be induced by overuse of an under-trained muscle and can result in localized soreness and stiffness for several days. Focal intense muscle spasm and pain can cause sudden-onset reduction in performance and, if primary, are usually alleviated by manipulation to relieve the muscle spasm, producing rapid amelioration of clinical signs.

Focal muscle soreness associated with localized swelling may be caused by intramuscular hemorrhage, muscle fiber tearing, or exertional rhabdomyolysis. Diagnosis of the cause may be determined by measuring serum muscle enzyme concentrations and by ultrasonographic evaluation (Figure 50-3). Hemorrhage results in an area of diffuse

Fig. 50-3 • Ultrasonographic image of the semimembranosus muscle of a 6-year-old Thoroughbred with acute-onset, severe left hindlimb lameness. The horse had palpable enlargement of the muscle and localized soreness. The increased echogenicity reflects hemorrhage.

increase in echogenicity within the muscle. This should be differentiated from hyperechogenic regions that result from chronic muscle fibrosis. Serum muscle enzyme concentrations are usually not elevated in those horses with hemorrhage, muscle fiber tearing, or fibrosis.

Damage to deep muscles of the hindquarters is difficult to identify because localizing clinical signs are frequently not apparent to alert the clinician to the possible site of damage. Thermographic evaluation can be useful to help identify superficial muscle injury.

Some horses with reduced performance have pain on palpation of the psoas muscles per rectum. Pain may be primary or secondary to pathological conditions of the lumbosacral or sacroiliac regions and is an indication for nuclear scintigraphic evaluation of the pelvic region and ultrasonographic examination of the lumbosacral vertebrae.

Sacroiliac Joint Injury

See Chapter 51 for further discussion of sacroiliac joint injury. Detailed anatomy of the sacroiliac joints is discussed elsewhere (see page 583).

The diagnosis of sacroiliac joint disease has tended historically to be a dustbin diagnosis, frequently made by exclusion when the clinical signs could not be explained by any other condition. The high incidence of pathological degenerative lesions found in the sacroiliac joints of TB racehorses²⁶ and in mixed-breed horses²⁷ indicates that degenerative disease of the sacroiliac joint is likely to be a clinically significant problem, but definitive diagnosis remains difficult. In a study of 74 horses with sacroiliac joint pain, affected horses were older than the normal clinic population, and there was a high proportion of Warmblood horses.² Horses used for dressage or show jumping predominated. Affected horses were also of great body weight and height. However, the condition is seen in horses used for all sports disciplines and has been recognized in competition ponies.

I recognize six clinical manifestations of sacroiliac joint region pain⁵: an acute onset of unwillingness to go forward when ridden; sudden onset of bucking and kicking out with one or both hindlimbs when ridden; insidious onset of reduced hindlimb impulsion and engagement; sacroiliac joint region pain in association with primary thoracolumbar region pain; unilateral or bilateral hindlimb lameness and secondary sacroiliac joint region pain; and sacroiliac region pain secondary to a previous ilial stress fracture.

Pathological changes of the sacroiliac joint include lipping, cortical buttressing, and osteophyte formation, together with enlargement of the joint surfaces. These signs are thought to be a response to chronic instability of the joints, although no evidence of ligamentous laxity has been identified.^{27,28} Erosion of the articular cartilage may also occur, but joint ankylosis has not been documented. A positive association has been recognized between the severity of the impingement of thoracolumbar dorsal spinous processes and lumbar transverse processes and the severity of sacroiliac lesions and also between the severity of articular process degeneration and the degree of pathological conditions of the sacroiliac region.

A separate entity of enthesophyte formation at the site of attachment of the sacroiliac ligaments has been described unassociated with pathological conditions of the sacroiliac

joints.²⁹ The clinical significance of this finding has not been well defined.

Subluxation of the sacroiliac joint is comparatively rare^{29,30} and results from acute, traumatic disruption of the dorsal sacroiliac ligament and the sacroiliac joint capsule. Subluxation should be differentiated from an acute ilial wing fracture resulting in depression of the ipsilateral tubera sacrale (see pages 564 and 567).

The prominence of the tubera sacrale and lumbar dorsal spinous processes varies between horses and in part reflects the conformation of the back and hindlimbs and the fitness of the horse. They may appear extremely prominent in a lean, fit event or endurance horse; however, this would be unusual in a normal dressage or show jumping horse. However, abnormal prominence could also result from poor development of the epaxial muscles in the lumbar region caused by the horse not using its back and hindlimbs properly. Poor muscle development may be a reflection of pain or of the horse's previous training: if the horse has never been asked to engage the hindlimbs properly and work through its back, these muscles will not be well developed.

Many apparently clinically normal horses have some degree of asymmetry of the height and/or shape of each tubera sacrale and the overlying soft tissues. Careful clinical appraisal of a small proportion of these horses may reveal subtle hindlimb gait abnormalities and mild discomfort induced by pressure applied over the tubera sacrale or by picking up one hindlimb and swaying the horse on the other. These findings are more likely to be detected in horses that are not fully fit and are often ameliorated when the horse is fitter and has greater muscle support. They may reflect mild instability of the sacroiliac joints but are not necessarily synonymous with degenerative change. Mild secondary sacroiliac joint region pain is often seen in association with hindlimb proximal suspensory desmitis.

Pain associated with the sacroiliac joints may be present despite symmetry of the tubera sacrale, is usually a bilateral condition, and is rarely associated with unilateral hindlimb lameness.² Pain often manifests as reduced performance, failure properly to engage the hindlimbs, and back stiffness. Signs are often greatly accentuated when the horse is ridden. In horses with mild clinical signs, the loss of hindlimb power and lack of suppleness through the horse's back may be much easier for the rider to feel than for an observer to appreciate. The rider may feel that he or she is being thrown forward in trot. Gait irregularities may be most apparent as the horse changes direction through a tight circle. Specific lateral movements such as half pass or sequence flying changes may be difficult. The quality of the canter is often worse than the trot. The horse may become progressively more unwilling to work under saddle and start to resist.

A comprehensive clinical evaluation is essential to preclude other conditions that may present similarly, such as bilateral distal hock joint pain. Precluding the hindlimbs as a potential source of pain by performing perineural analgesia of the tibial and fibular nerves and intraarticular anesthesia of the femorotibial and femoropatellar joints of one hindlimb may be necessary to see whether lameness becomes apparent in the contralateral limb.

Using a 15-cm needle inserted on the midline at the lumbosacral space and directed approximately 20 degrees

caudally, local anesthetic solution (up to 20 mL/side) can be infiltrated in the direction of the sacroiliac joints (see page 589). This may improve clinical signs in some horses and resulted in clinically significant change in 95 of 108 horses with suspected sacroiliac pain in which local analgesia was performed.⁵ However, false-negative results do occur.

Nuclear scintigraphic examination may facilitate diagnosis by helping to preclude the presence of other clinically significant causes of poor hindlimb action and by giving a positive indication of abnormalities of the sacroiliac joints.^{10-15,31,32} Profile analysis and quantitative evaluation using regions of interest are required for accurate diagnosis. The results ideally should be compared with horses of similar age and work history because of apparent significant age-related variability between clinically normal horses.¹¹ Considerable overlap in ratios of RU between each sacroiliac joint region and a standard reference site also occurs in clinically normal horses, horses with lameness unrelated to the sacroiliac joint, and horses with clinical signs compatible with sacroiliac joint disease.³² However, RU is bilaterally symmetrical in a normal horse. Excessive motion during image acquisition can result in images that are not of diagnostic quality and may mimic abnormalities; therefore images ideally should be acquired dynamically, and motion correction software should be used.¹¹ Residual radiopharmaceutical in the bladder may also confound interpretation. Abnormalities are recognized as abnormal patterns of RU (Figure 50-4) and asymmetrical ratios of RU between the left and right sacroiliac joint regions.²⁸ Care must be taken to differentiate between uptake in the tubera sacrale and uptake associated with the region of the sacroiliac joints.

Radiographic examination requires general anesthesia and can be frustrating because superimposition of abdominal viscera can preclude evaluation of the sacroiliac

joints.^{6,33} However, detection of joint space irregularities and spur formation on the caudal aspect of the joints are poor prognostic indicators.

Ultrasonographic examination should be performed transcutaneously to evaluate the dorsal sacroiliac ligaments^{8,9,34,35} and per rectum^{2,8} to assess the sacroiliac joints and to eliminate as potential diagnoses pathological conditions of the lumbosacral vertebrae. Irregularities of the caudal aspect of the sacroiliac joint may be identified.

Management is essentially palliative, and prognosis is generally inversely correlated with the severity of clinical signs. Local infiltration³³ of a phenol-based sclerosing agent, P2G (phenol, glucose, glycerin), or a combination of corticosteroids (methylprednisolone acetate, 200 mg) and Sarapin (High Chemical Company, Levittown, Pennsylvania, United States) appears to provide relief in some horses. Some horses benefit from treatment with nonsteroidal antiinflammatory drugs (NSAIDs), which provide partial pain relief, enabling the horse to work better and develop increased muscle strength. Daily work on the lunge using side reins, a Pessoa or a chambon, together with exercise in a cage horse walker in which the horse is free and not tied, and no ridden exercise for several weeks may be of substantial benefit. Acupuncture therapy helps some horses. Affected horses should be maintained in work at all times to maintain muscular fitness. Horses with acute problems respond best.

Sacroiliac joint disease may occur with other conditions; therefore careful appraisal of the whole horse is essential if a successful management strategy is to be achieved.^{2,5} Nuclear scintigraphic evaluation should include the thoracolumbar region. Concurrent impingement of dorsal spinous processes in the midthoracic, caudal thoracic, or cranial lumbar regions may occur with or without associated pain (see page 598). Infiltration of local anesthetic solution between or around the impinging dorsal spinous processes may be necessary to determine their contribution to the clinical problem. Careful evaluation of the synovial intervertebral articulations, especially close to the thoracolumbar junction, is also important. Occasionally sacroiliac disease has been seen together with OA of the coxofemoral joints. This warrants a guarded prognosis.

Desmitis of the Dorsal Sacroiliac Ligament

Desmitis of the dorsal sacroiliac ligament has been recognized in horses that have back pain, with or without focal pain on palpation.^{31,32} Usually lesions have been restricted to one side and have been characterized by ultrasonography as enlargements of the ligament and disruption of normal architecture, with hypoechoic regions in transverse images and loss of parallel alignment of echoes in longitudinal images. Enthesophyte formation may occur on the tubera sacrale. Such lesions have been seen alone or with other causes of back pain.

New Bone on the Caudal Aspect of the Wing of the Sacrum

A few mature competition horses used for dressage or show jumping have insidious onset loss of hindlimb action, progressing to unwillingness to maintain a proper trot. These horses have appeared considerably worse when ridden compared with evaluation in hand or on the lunge. The horses have shown abnormal sensitivity to palpation in the

Fig. 50-4 • Dorsal delayed (bone) phase scintigraphic image of a 9-year-old Warmblood dressage horse with clinical signs compatible with chronic sacroiliac joint disease. The horse's performance was markedly improved by periarticular infiltration of local anesthetic solution around the sacroiliac joints. There is increased radiopharmaceutical uptake in the region of both the left and right sacroiliac joints. The horse failed to respond to treatment, and a diagnosis of osteoarthritis of the sacroiliac joints was confirmed post mortem.

general areas of the sacroiliac joints. However, careful analysis of nuclear scintigraphic images has shown relatively normal radiopharmaceutical uptake in the region of the joints themselves but increased uptake abaxial to the joints. The horses have responded poorly to treatment with NSAIDs or other analgesic drugs. Post mortem examination has revealed spurs of new bone on the wings of the sacrum just caudal to the auricular surface but not involving the sacroiliac joint itself.^{26,27} This has been seen in association with fusion of the transverse processes of caudal lumbar vertebrae and osseous proliferation involving intervertebral foramina or synovial articulations.

Lumbosacral Joint

The clinical signs referable to lumbosacral pathology are difficult to differentiate from those associated with sacroiliac joint region pain and lesions in the thoracolumbar region. Moreover, lumbosacral pathology may coexist with sacroiliac or thoracolumbar lesions; therefore systematic radiographic, scintigraphic, and ultrasonographic evaluation of all areas should be performed. Lesions of the lumbosacral joint may be present in asymptomatic horses²⁶; thus determination of the potential clinical significance of abnormalities is not always easy. Radiographic examination of the lumbosacral joint is only possible with the horse in dorsal recumbency under general anesthesia. Lesions of the intertransverse joints are not uncommon, but their clinical significance is unclear. Nuclear scintigraphy is not particularly sensitive for detection of lesions of the lumbosacral joint largely because of the large overlying muscle mass resulting in shielding.

The lumbosacral joint and the intertransverse joints are evaluated ultrasonographically per rectum (Figure 50-5). The transrectal ultrasonographic appearance of the lumbosacral joint was assessed in 43 horses with no history or clinical evidence of back pain or hindlimb lameness.³⁶ In

the majority of horses (34/43, 79.1%) the lumbosacral disk had uniform or mildly heterogeneous echogenicity. Variations included hyperechogenic regions within the lumbosacral disk with or without an acoustic shadow, and mild or moderate irregularity of the opposing surfaces of the last lumbar and the first sacral vertebral bodies. Marked irregularity of the bony surfaces or marked disruption of the lumbosacral disk was not seen in any horse. The mean distance between the ventral aspects of the last lumbar and first sacral vertebrae was 14.2 mm (range: 7.1 to 26.5 mm). The degree of protrusion of the ventral aspect of the lumbosacral disk ranged from 0 to 5 mm (mean: 1.32 mm). The mean angle between the ventral surfaces of the last lumbar and first sacral vertebrae was 147 degrees (range: 118 to 165 degrees). There was no significant effect of the age, breed, gender, or size of the horses on either subjective findings in the lumbosacral joint or objective measurements.

Abnormalities that may be of clinical significance include:

1. Congenital lumbosacral ankylosis with reduced size or absence of the intervertebral disk
2. Focal loss of echogenicity of the intervertebral disk consistent with disk degeneration
3. Large focal hyperechogenic regions in the intervertebral disk consistent with dystrophic mineralization
4. Ventral herniation of the intervertebral disk
5. Ventral subluxation of the sacrum
6. Osseous irregularities of the intertransverse articulation(s)

Lesions of the lumbosacral joint are treated by deep paramedian injection^{3,35,37,38} of corticosteroids with Sarapin (High Chemical Company) or local anesthetic solution under ultrasound guidance. The needle is inserted 4 cm from the median plane on a line connecting the cranial aspects of the tubera coxae. The needle is directed obliquely caudally and is inserted under the ilial wing until contact is made with bone in the vicinity of the axial aspect of the lumbosacral intertransverse joint. This is repeated on the left and right sides. Success of treatment is highly variable, but is often transient. Modification of the work program as discussed in Chapter 52 (see page 605) is also important.

Aortoiliacofemoral Thrombosis

Aortoiliacofemoral thrombosis is a relatively uncommon cause of exercise-induced hindlimb lameness of variable severity.³⁹ Clinical signs may be sudden and severe in onset or subtle initially and slowly progressive. Horses of all ages may be affected. The incidence is higher in male horses than mares. The pathogenesis is unknown.

Clinical signs vary depending on the site(s) of thrombus formation, its size, and the degree of vessel occlusion. Lesions occur most commonly at the terminal aspect of the aorta, but they may also involve the internal and external iliac arteries and the femoral arteries, unilaterally or bilaterally. Lesions restricted to the femoral artery have not been documented. With mild lesions, the horse may show poor performance, early fatigue, or slight loss of hindlimb action during a work period. If the lesion(s) is predominantly unilateral, the horse may show episodic hindlimb lameness induced by work. With more advanced lesions, progressive shortening of hindlimb stride may occur with exercise,

Fig. 50-5 • Ultrasonographic image of the lumbosacral joint of a 10-year-old show jumper with a history of loss of performance. Dorsal is to the top and cranial to the right. The margins of the lumbosacral joint are poorly defined, and there is a large area of reduced echogenicity within the intervertebral disk. There are also focal hyperechogenic foci. This is consistent with intervertebral disk degeneration.

Fig. 50-6 • A 9-year-old gelding with aortoiliac thrombosis. Clinical signs were provoked by just 5 minutes of lunging exercise. **A**, The horse repeatedly flexed each hindlimb, stamping it to the ground. No evidence of sweating over the hindquarters was apparent, but the horse was sweating profusely over the neck and flanks. **B**, The saphenous vein cannot be seen because of delayed filling.

followed by development of distress and sweating, except over the hindlimbs (Figure 50-6, A). If the horse is allowed to stop, it may repeatedly flex its hindlimbs and stamp the feet to the ground. The affected limbs feel cool, and delayed filling of the saphenous veins may be seen (see Figure 50-6, B), with reduced pulse amplitudes in the dorsal metatarsal artery. Clinical signs usually resolve if the horse is allowed to stand still for a few minutes.

In horses with advanced thromboembolism, it is usually possible to palpate a thrombus per rectum in the terminal aspect of the aorta, which feels abnormally firm. Pulses in the iliac arteries may be reduced or absent. With less advanced lesions, diagnostic ultrasonography is required for identification of the lesion (Figure 50-7). Ultrasonography is also useful to determine the extent of the lesions.⁴⁰ Examination of part of the femoral artery can be performed transcutaneously on the medial aspect of the crus,^{3,41} and the use of Doppler ultrasonography to measure blood flow characteristics should help to determine whether a more proximal site of obstruction exists.^{40,42}

First-pass radionuclide angiography can be used to determine blood flow in the aorta and iliac arteries^{22,43} and also the femoral arteries. However, the sensitivity of the technique for detecting subtle lesions has yet to be determined.

The aims of treatment are to try to prevent further thrombus formation and to promote the development of a collateral blood supply for adequate perfusion. No drugs are available that alter a preformed thrombus. Treatment rationale has been based on pain relief and the use of antiinflammatory drugs, platelet inhibitors, anthelmintics, fibrinolytic agents, and anticoagulant drugs. Those most commonly used include phenylbutazone (2.2 mg/kg twice daily for 2 months), aspirin (5 mg/kg daily for several months), and isoxsuprine (1 mg/kg twice daily for 3 months). Successful treatment presumably is based on development of an effective collateral blood supply.

I have successfully managed some mildly affected horses with long-term aspirin therapy, but horses with more severe lesions are usually refractory to treatment. Only two of 29 horses returned to former athletic function, with resolution of clinical signs, following medical treatment.³⁸ Surgical removal is feasible,^{44,45} although the rate of complications is high. Surgery was successful in 53% of 17 horses, but four horses had postoperative myopathy, two of which were humanely destroyed, and a fifth horse sustained a fatal femoral fracture during recovery from anesthesia.⁴⁵ Reocclusion of the treated vessels may occur.

Fig. 50-7 • Longitudinal ultrasonographic images of the terminal aorta of a normal horse (**A**) and a horse with aortoiliac thrombosis (**B**). Cranial is to the left. There is a large echogenic mass in the aorta of the clinically affected horse. **C**, Transverse ultrasonographic image of the right external iliac artery. This appears normal, but an extensive thrombus was identified farther distally at post mortem examination.

Coxofemoral Joint

The coxofemoral joint is rarely a source of pain causing lameness in the horse.

Dysplasia

Dysplasia of the coxofemoral joint is rare, usually occurs bilaterally, and predisposes relatively young horses to develop OA. The prognosis for athletic function is poor. Dysplasia may be a heritable condition in the Norwegian Dole.

Osseous Cystlike Lesions

An osseous cystlike lesion occasionally has been identified in young horses and associated with lameness.⁴⁶ The lesions have resulted in chronic lameness.

Osteoarthritis

OA of the coxofemoral joint is an unusual cause of hindlimb lameness in the horse, usually occurring unilaterally but occasionally bilaterally. OA may occur secondary to dysplasia, rupture of the teres ligament (see page 582), or trauma.

Lameness varies from moderate to severe. The horse resents flexion of the limb and is unwilling to stand on the limb for long periods with the contralateral limb picked up. The degree of gluteal muscle disuse atrophy may be more than that from pain in the more distal part of the limb. Lameness may be characterized by a tendency for the horse to move on three tracks.

Intraarticular analgesia usually, but not always, improves lameness, but it is rarely alleviated fully.

Nuclear scintigraphic evaluation may help in highlighting the coxofemoral joint as abnormal, especially if the results of intraarticular analgesia are equivocal. However, it is important to be aware that loss of muscle over the hindquarter of the lame limb may confound image interpretation. I have found it useful to evaluate ratios of RU in the region of the coxofemoral joint and another standardized location and compare this with values for normal horses. Caudal oblique images can be helpful. The clinician should be aware that RU associated with a normal coxofemoral

joint is much less than that of the cranial and caudal parts of the greater trochanter of the femur.

Definitive diagnosis of OA requires radiographic examination, and high-quality radiographs can only be achieved with the horse in dorsal recumbency under general anesthesia. Abnormalities include periarticular osteophyte formation, new bone formation along the femoral neck, lucent zones in the subchondral bone of the acetabulum or femoral head, and loss of congruity between the acetabulum and femoral head (Figure 50-8). Care should be taken not to confuse the depression in the femoral head and underlying radiolucent zone at the site of insertion of the teres ligament as a lesion.

Intraarticular medication of a coxofemoral joint with radiological abnormalities has yielded disappointing results. The prognosis for return to athletic function is guarded.

Trochanteric Bursitis

Trochanteric bursitis has been described in the older literature, but the Editors have not recognized this condition. The condition is discussed elsewhere (page 552).

Luxation with or without Secondary Upward Fixation of the Patella

Luxation or subluxation of the coxofemoral joint is an unusual injury and can occur as a primary injury or secondary to an unstable fracture of the ilial shaft. The trauma causing luxation also can result in articular fractures of the acetabulum. Permanent upward fixation of the patella may develop as a sequela because of displacement of the femur. The femur is displaced proximally; therefore the greater trochanter of the femur appears higher on the lame limb. However, this can be difficult to assess because the horse is usually reluctant to bear weight on the limb. Upward fixation of the patella results in an abnormally straight hindlimb stance and an inability to flex the limb. The diagnosis can be confirmed radiologically, and with high-output x-ray machines, diagnostic radiographs can be obtained with the horse standing; however, determining whether concurrent

Fig. 50-8 • Ventrodorsal radiographic image of the left coxofemoral joint of a 9-year-old steeplechaser with osteoarthritis. The horse had raced successfully the previous season, but it now showed moderate left hindlimb lameness at trot and carried the left hindlimb at canter. Note the marked periarticular osteophyte formation on the pelvic acetabulum (arrows) and the irregular subchondral bone opacity.

fractures exist may be difficult. Ultrasonography can also be used to verify the presence of subluxation.⁴⁷ The prognosis for athletic function is hopeless.

Rupture of the Teres Ligament

Rupture of the teres ligament results from trauma. It has been seen in a horse that tried to get up prematurely from general anesthesia while the limbs were still restrained in hobbles, and in other circumstances in which a hindlimb has become trapped. Lameness is severe, with the horse being unwilling to bear weight on the limb. Secondary OA rapidly ensues. Definitive diagnosis is only possible post mortem. The prognosis for athletic function is hopeless.

Displacement of the Femoral Head

Displacement of the femoral head has been seen occasionally in young horses with severe lameness and reluctance to bear weight on the limb. Diagnosis is confirmed radiologically. The prognosis is hopeless.

Fig. 50-9 • Lateral (A) and caudal (B) scintigraphic images of the right femur of a 7-year-old Warmblood dressage horse with sudden onset of severe right hindlimb lameness. In the lateral image (A), there are two areas of focal intense increased radiopharmaceutical uptake (IRU) in the region of the third trochanter of the femur; IRU is seen within the third trochanter in the caudal image. This is consistent with a fracture of the third trochanter of the femur.

Fracture (or Enthesopathy) of the Third Trochanter of the Femur

Fracture of the third trochanter of the femur is a relatively unusual injury, resulting in acute-onset severe lameness that often improves rapidly with box rest. In a lean, poorly muscled horse, eliciting pain by palpation may be possible, but in a well-muscled Warmblood type, eliciting pain is usually not possible, even in acute injuries. No particular gait characteristics are apparent. Nuclear scintigraphy is particularly valuable for tentative diagnosis of a fracture^{10,16} characterized by IRU (Figure 50-9) and sometimes a change in the pattern of uptake. Diagnosis may be confirmed radiologically, but good-quality radiographs in large horses can only be achieved under general anesthesia. Oblique radiographic images can be acquired standing in small horses. Fractures are often longitudinal, occurring at the base of the trochanter, but horizontal fractures have been seen.^{6,16} Displacement is usually minimal. Diagnostic ultrasonography is sometimes useful to confirm a fracture and to exclude abnormalities of the superficial gluteal muscle, which inserts on the third trochanter. Insertional tears of this muscle may be associated with a similar scintigraphic appearance. Treatment is box rest for 2 months, followed by walking exercise for another month. Healing may occur by osseous or fibrous union. Prognosis is good.

Chapter 51

Diagnosis and Management of Sacroiliac Joint Injuries

Kevin K. Haussler

ANATOMICAL AND FUNCTIONAL FEATURES

The sacroiliac joint is a synovial articulation located at the junction between the ventral aspect of the wing of the ilium and the dorsal aspect of the wing of the sacrum (Figure 51-1). The sacroiliac joint functions in pelvic attachment to the axial skeleton, providing support during weight bearing and helping to transfer propulsive forces of the hindlimb to the vertebral column. The sacroiliac joint is an atypical synovial articulation because of hyaline cartilage on the sacral articular surface and a thin layer of fibrocartilage on the ilial articular surface.¹ The articular surfaces of the sacroiliac joint are nearly flat and closely apposed to support gliding movements. The sacroiliac articular surfaces diverge cranially at about 40 degrees from a transverse plane and are angled craniodorsally to caudoventrally at about 60 degrees from the horizontal plane. The joint capsule is thin and closely follows the margins of the sacroiliac articular cartilage. The sacroiliac joint capsule is reinforced ventrally by the ventral sacroiliac ligament.² A small amount (<1 mL) of synovial fluid is normally present in the joint.¹ Because of articular surface remodeling, the size and shape of the sacroiliac joint margins vary considerably according to age and body weight.³ Typically the sacroiliac joint outline is L-shaped, with the convex border directed caudoventrally.

(Modified from Dyce KM, Sack WO, Wensing CJG: *Textbook of veterinary anatomy*, ed 2, Philadelphia, 1996, Saunders.)

The pelvis is firmly attached to the axial skeleton by sacroiliac and sacrosomatic ligaments, which form a strong ligamentous sling (see Figure 51-1). The weight of the caudal aspect of the vertebral column is suspended from the sacroiliac ligaments, which function similarly to the fibromuscular sling found between the proximal aspect of the forelimb and the lateral thoracic body wall. Subsequently the sacroiliac articular cartilage may never be fully weight bearing, unlike most articular cartilage. The sacroiliac joint is supported by three pairs of strong ligaments: the dorsal, interosseous, and ventral sacroiliac ligaments. The dorsal sacroiliac ligament consists of dorsal and lateral portions (Figure 51-2). The dorsal portions form two round cords that span from the dorsal aspects of the tubera sacrale to the dorsal apices of the sacral spinous processes. The lateral portion forms a sheet of connective tissue that spans from the caudal margin of each tuber sacrale and iliac wing to the lateral border of the sacrum. The lateral portion of the sacroiliac ligament is continuous ventrally with the sacrosomatic ligament. The interosseous ligament of the sacroiliac joint is robust and consists of a series of vertical fibers that connect the ventral aspect of the wing of the ilium to the dorsal aspect of the wing of the sacrum (see Figure 51-1). The interosseous sacroiliac ligament provides the major resistance to vertically oriented weight-bearing forces acting on the sacrum. The ventral sacroiliac ligament interconnects the ventral aspects of the wings of the ilium and sacrum. The ventral sacroiliac ligament is thin and closely applied to the ventral margins of the sacroiliac joint capsule.

Neurovascular structures adjacent to the sacroiliac joint include the sciatic nerve, cranial gluteal nerve, and cranial gluteal artery and vein. These structures collectively travel through the greater sciatic foramen, ventromedial to the sacroiliac articulation (see Figure 51-2). The cranial gluteal artery and vein arise from the internal iliac vessels and travel over the ventral sacroiliac ligament and the caudomedial aspect of the sacroiliac joint before emerging at the greater sciatic foramen. The cranial gluteal artery and vein

continue dorsally into the gluteal musculature. The middle and accessory gluteal muscles originate from the dorsal aspect of the ilial wing and have attachments near the caudomedial aspect of the sacroiliac joint. Within the pelvic canal, a portion of the internal obturator and iliacus muscles covers the ventral sacroiliac joint margins.

The robust sacroiliac and sacrospinous ligaments limit motion at the sacroiliac articulations.⁴ Shear forces would be expected at the sacroiliac articular surfaces more than compressive forces, which are common in most limb articulations.⁵ Sacroiliac joint movements are restricted to small amounts of approximately 1 degree during flexion (nutration) and extension (counternutation), with an apparent axis of rotation oriented transversely near the caudomedial aspect of the joint.^{6,7} As a result of coupled sacroiliac joint motion of flexion-extension, lateral bending, and axial rotation combined with concurrent pelvic deformation, motion at the sacroiliac joints is complex.⁸ Lateral movements at the sacroiliac articulations are severely restricted, primarily because of lateral attachments of the ventral sacroiliac ligaments and, to a lesser degree, the lateral portion of the dorsal sacroiliac ligaments and the sacrospinous ligaments. The wings of the ilium overlay the sacral articular surfaces dorsally and laterally, which precludes any axial rotation from occurring at the sacroiliac joint. Dorsal displacement of the ilial wings is limited by the robust interosseous ligament, the ventral sacroiliac ligament, and lateral portion of the dorsal sacroiliac ligaments.⁹ Propulsive forces of the hindlimb are transmitted dorsally and cranially to the vertebral column by the articular configuration of the overlapping and divergent ilial wings over the sacrum and by reinforcement from the dorsal and interosseous sacroiliac ligaments. The dorsal sacroiliac ligament also provides resistance against contraction of the powerful longissimus muscle and robust thoracolumbar fascia, which attach along the cranial border of the ilial wing.

PATHOLOGICAL CONDITIONS

The antemortem diagnosis of sacroiliac joint injury in horses is difficult and often based on a diagnosis of exclusion.¹⁰ Diagnosis is complicated by anatomical inaccessibility, mild chronic clinical signs so that opportunities for correlation with necropsy findings are uncommon, and ongoing controversies over the clinical relevance and prevalence of pathological conditions of the articular surface and ligaments.⁴ Terms used to describe pathological conditions of the sacroiliac joint include sacroiliac sprain or instability,^{11,12} sacroiliac joint subluxation,¹³ and sacroiliac arthrosis.^{14,15} The prevalence of pathological conditions of the sacroiliac joint in performance horses is probably high, and many may go undiagnosed.^{4,14,16} In a necropsy survey of 36 Thoroughbred (TB) racehorses with no known back or sacroiliac joint problems, we observed various degrees of degenerative sacroiliac joint changes in all specimens.¹⁷ The clinical importance of osseous sacroiliac joint pathological conditions is difficult to determine because many presumed normal horses have osteoarthritic changes similar to horses with known back or sacroiliac problems.^{1,4} Possibly the majority of sacroiliac joint pathological conditions are subclinical; however, if similar findings were noted in any other musculoskeletal location, the articular changes would be considered clinically relevant and a

likely contributing cause of lameness. A more likely scenario is that deep sclerogenous pain (e.g., vertebral or sacroiliac joint osteoarthritis [OA]) is often poorly localized and perceived as deep aching pain, based on reports of similar pathological conditions of the sacroiliac joint in affected people. Clinically the most common reported signs of sacroiliac joint disorders in horses are poor performance, lack of impulsion, and a mild, chronic hindlimb lameness, which can easily be overlooked or dismissed as not clinically relevant.^{4,18} Obvious signs of lameness and localized pain or inflammation are not typical clinical characteristics of sacroiliac joint or pelvic injuries, unless pelvic fractures or substantial joint disruption is present.

OA of the sacroiliac joints is usually a bilateral condition and may be present despite symmetry of the tubera sacrale.¹⁹ Degenerative changes of the sacroiliac joint include (in apparent order of increasing severity) articular surface lipping, cortical buttressing, articular recession, osteophytes, and intraarticular erosions (Figure 51-3). In our survey of 36 TB racehorses, sacroiliac degenerative changes were classified as mild in 8% of specimens, moderate in 61%, and severe in 31%. Age was not associated with overall prevalence or severity of sacroiliac joint degenerative changes.¹⁷ Osseous changes are usually bilaterally symmetrical and most commonly located at the caudomedial aspect of the articulation.^{1,17} The pathogenesis of proliferative sacroiliac joint changes is uncertain, but it is thought to be related to chronic instability resulting in gradual remodeling and subsequent enlargement of the caudomedial joint surfaces. Histologically the caudomedial extensions consist of apparently normal cancellous bone.⁴ Articular cartilage erosion is a lytic process of articular surfaces that presumably leads to eventual sacroiliac joint ankylosis.¹⁷ However, ankylosis of the sacroiliac joint is rare, which is surprising based on the limited joint motion and the potential severity of osseous pathological conditions present.^{1,17,20} Fibrous interconnections between the articular surfaces have also been reported in presumed normal sacroiliac joints.¹ Articular cartilage discoloration, a presumed indicator of sacroiliac joint degeneration, is

Figure 51-3 • Bilateral osteoarthritis of the sacroiliac articulations (ventral view). Severe proliferative changes of the caudomedial third of the sacroiliac joints (arrows) in an 8-year-old racing Thoroughbred gelding that was euthanized because of an acute colic episode. Normal sacroiliac joint margins are typically smooth and linear as represented by the cranial half of the sacroiliac articulations.

common in racehorses, but it has a reported higher prevalence in Standardbreds (STBs) compared with TBs.¹⁴ One theory is that these changes are caused by differences in pelvic and sacroiliac joint biomechanics associated with pacing and trotting (i.e., lateral bending or shear forces) in STBs compared with galloping (i.e., flexion and extension movements) in TBs.²¹ Biomechanical studies are warranted to support or refute these claims.

Sacroiliac desmitis, the most common soft tissue injury, was documented by ultrasonography in the dorsal portion of the dorsal sacroiliac ligament.²² A diagnosis of sacroiliac desmitis is based on loss of normal echogenicity on a transverse image and a decrease in parallel fiber pattern on a longitudinal image. Sacroiliac ligament injuries usually occur because of acute trauma, but few horses with documented injury were reported.^{17,23}

Complete sacroiliac ligament disruption is most likely caused by substantial trauma, such as flipping over backward, or catastrophic musculoskeletal injuries associated with race training.¹⁷ Post mortem findings associated with traumatic sacroiliac ligament injuries include either unilateral or bilateral joint capsule disruption, avulsion fractures of the sacroiliac ligament attachment sites, and noticeable sacroiliac joint laxity. Dorsal or ventral sacroiliac ligaments can be affected, depending on the inciting mechanism of injury.^{9,17,23} Complete sacroiliac ligament disruption may produce unilateral or bilateral dorsal displacement of the tubera sacrale, depending on the extent of injury (Figure 51-4).

Acute sacroiliac ligament injuries have been reported to contribute to development of chronic sacroiliac joint instability.^{11,23} However, the presence and relevance of chronic sacroiliac ligament injury and sacroiliac joint laxity are controversial. Rooney et al^{23,24} documented chronic sacroiliac joint injuries of the cranial portion of the ventral sacroiliac ligaments, which were found to be elongated or torn on the affected side. Desmitis of the insertion site of

the dorsal portion of the dorsal sacroiliac ligament at the insertion on the tuber sacrale was reported.⁹ In other studies osseous changes were found at the caudomedial sacroiliac joint margins in horses suspected of having chronic sacroiliac injury; however, no obvious sacroiliac ligament laxity was observed.^{4,11,12} Radiologically some of these horses had an apparent increase in the sacroiliac joint space; however, no visible sacroiliac ligament injury, joint laxity, or subluxation was observed at necropsy.^{4,12} In our necropsy survey of 36 TB racehorses, no evidence of chronic ligament injury or sacroiliac joint subluxation was observed.¹⁷ However, this could be related to the previous removal of horses from race training with poor performance or hindlimb lameness associated with chronic sacroiliac joint injury.

The pathogenesis of apparent spontaneous or insidious differences in tuber sacrale height needs to be further researched.⁴ Unilateral or bilateral dorsal displacement of the tubera sacrale is often a presumed indication of sacroiliac subluxation.²⁵ In my opinion, variable degrees of tubera sacrale height asymmetry occur frequently and may be caused by chronic asymmetric muscular or ligamentous forces acting on the malleable osseous pelvis and not by direct sacroiliac ligament injury.²⁶ Tubera sacrale height asymmetries are common in horses without documented sacroiliac joint injuries (see Figure 51-4). In only a few horses have tubera sacrale height asymmetries been associated with chronic sacroiliac ligament injuries or joint laxity.²⁴ In a study of 4-year-old STB trotters with tubera sacrale height asymmetries of more than 1 cm, associations were found with poor performance, but otherwise the asymmetry was of questionable clinical importance.¹⁶ If substantial tubera sacrale height differences are identified, which side is affected is unclear and difficult to determine: the seemingly dorsally displaced tuber sacrale or the less prominent tuber sacrale on the opposite side.^{4,16} Presumed sacroiliac joint subluxation produces an elevated tuber sacrale on the affected side, whereas complete ilial wing fractures (the most common type of pelvic fracture) typically produce a palpably depressed tuber sacrale on the affected side.²⁷

Figure 51-4 • Photograph of tubera sacrale height asymmetry (caudal view). The tuber sacrale on the right side is dorsally displaced, with apparent gluteal muscle symmetry. (Courtesy Al Kane, Ft. Collins, Colo, United States.)

CLINICAL PRESENTATION

Horses with sacroiliac joint injuries vary in clinical presentation, usually based on the duration and extent of injury present. The history of horses with acute sacroiliac joint injury usually includes slipping, falling, or trauma that causes pelvic rotation or induces high stresses.²⁵ Horses with acute sacroiliac joint injuries often have noticeable lameness and localized sensitivity to palpation of the surrounding soft tissues or tubera sacrale (Figure 51-5), which must be differentiated from other sources of back, pelvic, or hindlimb pain. Diagnosis of acute sacroiliac ligament rupture and subsequent sacroiliac joint subluxation or luxation is based on history, physical examination, and diagnostic imaging. Because the majority of horses have some degree of tuber sacrale height asymmetry, a diagnosis of acute sacroiliac joint subluxation can only be confirmed if symmetry of the tuber sacrale was documented immediately before the injury, and subsequently gross asymmetry of the tubera sacrale is noted with localized signs of pain or inflammation.

Figure 51-5 • Diagram of sacroiliac joint provocation test (dorsal view). Firm pressure is applied bilaterally with both hands, compressing the dorsal aspects of the tubera sacrale.

Important historical findings in horses with chronic sacroiliac joint injuries usually involve repetitive overuse versus a single traumatic event.¹⁴ The most consistent clinical feature of chronic sacroiliac joint injury is a prolonged, nonprogressive history of reduced or poor performance.⁴ In a recent study Warmblood horses involved in dressage and show jumping were most commonly affected.²⁸ Changes in performance included back stiffness, unwillingness to work, lack of impulsion from one or both hindlimbs, and refusing jumps. The duration of clinical signs varied from 1 month to more than 1 year, and to an untrained observer many of the horses appeared clinically normal.²⁸ Subtle gait asymmetries may be noticed at slow speeds during ground work or dressage movements and in harness horses at racing speeds.⁴ Signs are often markedly accentuated when the horse is ridden, especially with changes in direction through tight circles in trot, half passes, or flying lead changes in canter.¹⁹ Chronic sacroiliac joint injuries usually produce a low-grade or intermittent hindlimb lameness or stiffness that cannot be localized by routine lameness examination techniques and is improved only temporarily with antiinflammatory medications.⁴ The affected sacroiliac joint usually corresponds to the side of lameness or reduced cranial swing phase of the affected hindlimb, but bilateral gait abnormalities can occur. Gait asymmetries involve subtle differences in pelvic movement or reduced hindlimb flexion or stride lengths. Affected horses commonly resent standing on the affected hindlimb while the contralateral hindlimb is lifted off the ground during hock flexion or shoeing.¹⁸ Affected horses may also drag a hind foot and have mild hindlimb abduction before hoof contact (i.e., plaiting or rope walking).⁴ Disuse atrophy of the gluteal musculature is an inconsistent finding; however, some horses have pelvic asymmetry with a lower tuber coxae and noticeable gluteal muscle atrophy on the affected side.^{4,29} Observation of the tubera sacrale may reveal unilateral or bilateral (i.e., hunters' or jumpers' bumps) differences in height or dorsal prominence (see [Figure 51-4](#)). Unilateral or bilateral prominence of the tubera sacrale varies between horses and may be related to

conformation of the back or pelvis.¹⁹ Poor thoracolumbar epaxial or gluteal muscle development may cause the tubera sacrale to be more visually prominent in horses that have chronic back or sacroiliac pain or lack proper collection and engagement of the hindlimbs.

Two clinical manifestations of sacroiliac joint dysfunction were proposed.³⁰ Horses in one category exhibit pain and poor performance that is responsive to local analgesia, tubera sacrale symmetry, and poorly defined pelvic or sacroiliac joint pathology (i.e., functional instability caused by altered neuromotor control). Those in the second category display poor performance and marked gait alterations, bony and soft tissue asymmetry, small improvements with local analgesia, and pathological changes associated with chronic joint instability (i.e., structural instability). Further research is needed to assess whether these proposed categories are clinically useful and distinct or whether they represent a continuum of sacroiliac joint dysfunction.

PHYSICAL EXAMINATION

Clinical signs of sacroiliac joint injury vary and may occur in conjunction with other sources of hindlimb lameness or poor performance. The sacroiliac joint is relatively inaccessible to direct evaluation or palpation, and the normally small amount of sacroiliac joint motion is difficult to detect clinically.³¹ Horses with acute sacroiliac joint injuries may have localized sensitivity to palpation of the surrounding soft tissues in the dorsal aspect of the croup.⁴ A localized region of edema may occasionally be palpated over the lumbosacral junction³²; however, this is not a specific finding related to sacroiliac joint injury. Protective muscle spasms may be palpated in the adjacent middle gluteal musculature and the vertebral portions of the biceps femoris, semitendinosus, and semimembranosus muscles. In horses with acute sacroiliac injuries, asymmetry in gluteal muscle development is uncommon, unless pronounced osseous pelvic asymmetry is also present. Pain may be elicited by applying firm digital pressure over the dorsal aspects of the tubera sacrale or caudal lumbar and sacral dorsal spinous processes. Unilateral or bilateral prominence of the tubera sacrale may be noted, but it is not usually clinically relevant unless associated with clinical signs of localized pain or inflammation, or positive findings on diagnostic imaging are found (e.g., scintigraphy). In horses with sacroiliac joint pain, the tubera sacrale may appear grossly symmetrical despite asymmetric croup musculature.²⁸ Normally the tubera sacrale move in unison during pelvic movement in locomotion. A palpable or visible independent movement of the tubera sacrale at a walk or during treadmill locomotion indicates sacroiliac joint subluxation or a complete pelvic fracture. Crepitus associated with sacroiliac joint instability or complete pelvic fracture may be palpable or auscultated with a stethoscope placed over the gluteal musculature as the pelvis is repeatedly rocked laterally. Horses with acute sacroiliac joint injuries may also resent flexion of the hindlimb on the affected side or rectal palpation in the region of the sacroiliac joint.

Horses with chronic sacroiliac joint injuries often have compensatory stiffness and pain in the proximal aspect of the hindlimb.²⁵ Concurrent forelimb or hindlimb lameness

needs to be excluded with perineural and intraarticular diagnostic analgesia.²⁸ Upper limb flexion is often negative.⁴ Mild discomfort can be produced in some horses by picking up one pelvic limb and inducing a gentle lateral sway on the weighted limb.¹⁹ Farriers often complain that affected horses have difficulty or refuse to stand while being shod, presumably because of strain or pain induced in the affected single weight-bearing limb.²⁸ Rectal examination for chronic sacroiliac joint subluxation is usually unrewarding and will not be diagnostic unless bone proliferation, excess joint motion, or joint crepitus during externally applied movements is identified.²⁵ A pain response or palpable muscle hypertonicity in the iliopsoas muscles may be noted during rectal examination. Serum chemistry indicators of skeletal muscle injury or inflammation (i.e., creatine kinase [CK] and aspartate transaminase [AST]) are often negative.

The apex of the second sacral spinous process is a reliable landmark used to evaluate relative unilateral or bilateral tubera sacrale displacement. The robust dorsal portion of the dorsal sacroiliac ligament spans between the tubera sacrale and the sacral spinous processes. Normally the dorsal apices of the tubera sacrale and the second sacral spinous process lie in close apposition and follow the contour of the croup. Using palpation, ultrasonography, or radiology, a physical discrepancy in height often can be identified between the dorsal profile of the sacral spinous processes (which should remain constant, unless fractured) and the potentially dorsally or ventrally displaced tubera sacrale. In this manner, unilateral (i.e., tubera sacrale height asymmetry) or bilateral tubera sacrale displacement (i.e., hunters' or jumpers' bumps) can be diagnosed, depending on whether one or both tubera sacrale are elevated relative to the apices of the sacral spinous processes. Bilateral tubera sacrale displacement has an unknown clinical relevance and may occur without clinical signs in many high-level competition horses.³² Theoretically the hunters' or jumpers' bumps may provide a longer lever arm for the strong longissimus and thoracolumbar fascia to produce extension at the lumbosacral joint, resulting in increased impulsion and range of hindlimb motion, with subsequent improved performance.

Firm digital pressure applied to the dorsal aspect of each tuber sacrale was reported to produce a variable and inconsistent pain response.¹⁸ The tolerance to palpation and applied pressure to soft tissues and bony landmarks of the sacroiliac joint region are subjective assessments. Pressure algometry has the potential to quantify muscle or bone pain in horses with sacroiliac joint injuries.³³ Affected horses have lower mechanical nociceptive thresholds and greater left-right differences compared with control horses. In my experience, dramatic pain responses have been produced in affected horses with specific provocation tests, which are useful to establish a presumptive diagnosis of pelvic stress fracture or sacroiliac joint injury. The first procedure involves simultaneous manual compression of the dorsal aspects of both tubera sacrale, which induces a bending moment on the iliac wing and presumably compresses the sacroiliac articulations (see Figure 51-5). Acutely affected horses may have a dramatic reaction to this manipulation and demonstrate sudden hindlimb flexion and an apparent inability to bear weight in the hindlimbs when pressure is applied. Clinicians should gradually apply

increasing pressure because affected horses may actually collapse in the hindlimbs and fall to the ground if excess force is applied to the painful tubera sacrale. A negative response is characterized by minimal pain response and slight extension of the lumbosacral joint during manual compression of the tubera sacrale. This test is not specific for pathological conditions of the sacroiliac joint because horses with incomplete or stress fractures of the ilial wing may respond even more dramatically to the applied pressure.

A second procedure used to identify sacroiliac ligament injury involves rhythmically applying a ventrally directed force over the lumbosacral dorsal spinous processes to stress the supporting sacroiliac ligaments. This procedure requires the clinician to get up on an elevated surface (e.g., mounting block) so that the applied forces can be directed vertically over the sixth lumbar and second sacral dorsal spinous processes. Horses with sacroiliac ligament injuries would be expected to resent the induced movement because it specifically stresses the interosseous sacroiliac ligament (i.e., ligamentous sling of the sacropelvic junction). Horses with lumbosacral vertebral joint dysfunction (i.e., localized pain, reduced joint motion, and muscle hypertonicity without structural pathological conditions) may also resent this procedure. Rhythmically applied ventrally directed forces over the dorsal spinous processes at the sacrocaudal junction would be expected specifically to stress the dorsal portion of the dorsal sacroiliac ligament. A positive response to this test combined with positive ultrasonographic findings of desmitis of the dorsal sacroiliac ligament would be highly suggestive of clinically relevant sacroiliac ligament injury.

A similar procedure involves rhythmically applying a ventrally directed force over each tuber coxae to induce general sacroiliac and lumbosacral joint motion. A normal response to the induced movement is fluid vertical motion of the lumbosacral region, with an amplitude of 1 to 2 cm of dorsoventral movement measured over the lumbar dorsal spinous processes. Affected horses have a noticeable pain response, resent the induced movement, or have protective gluteal or sublumbar muscle spasms. The vertically directed force also induces movement at the lumbosacral junction, which must be differentiated from sacroiliac joint injury.

Additional procedures used to localize sacroiliac joint or ligament injuries involve indirectly evaluating pain and ligamentous laxity in the sacroiliac joint using laterally applied forces (Figures 51-6 and 51-7). These procedures are similar to valgus-varus stress tests used to evaluate collateral ligaments of the distal limb articulations. Caution should be taken not to apply excessive force because of the long lever arm action of the sacral apex on the sacroiliac ligaments, which can unduly stress unstable or partially torn ligaments or aggravate an acutely inflamed sacroiliac joint. The proposed mechanism of action of these tests is to use the base of the tail and sacrum as a handle to apply a lateral (horizontal plane) stress to the sacroiliac joint as the wing of the ilium is stabilized. The technique involves two parts. First, the base of the hand closest to the horse's head is placed over the lateral aspect of the tuber sacrale. The hand closest to the tail grasps the base of the tail head (the second and third coccygeal bones). The sacroiliac joints are then evaluated as firm pressure is simultaneously

Figure 51-6 • Diagram of second sacroiliac joint provocation test (dorsal view). **A**, Firm pressure is applied by both hands, pushing with the hand at the ipsilateral tuber sacrale away from the clinician while simultaneously pulling with the hand at the tail head toward him or her. **B**, Firm pressure is applied by both hands, pulling with the hand at the contralateral tuber sacrale toward the clinician while simultaneously pushing with the hand at the tail head away from him or her.

Figure 51-7 • Diagram of third sacroiliac joint provocation test (dorsal view). **A**, Firm pressure is applied by both hands, pushing with the hand at the tail head away from the clinician while simultaneously pulling with the hand at the contralateral ischial tuberosity toward him or her. **B**, Firm pressure is applied by both hands, pulling with the hand at the tail head toward the clinician while simultaneously pushing with the hand at the ipsilateral ischial tuberosity away from him or her.

applied by both hands, pushing with the hand at the tuber sacrale away from the clinician and pulling with the hand at the tail head toward him or her (see [Figure 51-6, A](#)). Theoretically this maneuver produces compression of contralateral sacroiliac articular surfaces and distraction of the ipsilateral sacroiliac articular surfaces.

The second portion of the technique involves repeating the procedure and reversing the direction of the applied forces (see [Figure 51-6, B](#)). The fingers of the hand closest to the horse's head are placed over the contralateral tuber sacrale, and the base of the hand closest to the tail is placed

against the ipsilateral base of the tail head (second and third coccygeal bones). The sacroiliac joints are again evaluated as firm pressure is applied by both hands, pulling with the hand at the tuber sacrale toward the clinician and pushing with the hand at the tail head away from him or her. Theoretically the contralateral sacroiliac articular surfaces are distracted, and the ipsilateral sacroiliac articular surfaces are compressed. A pain response to the induced movements may be identified unilaterally or bilaterally, depending on the extent of inflammation or injury present. In general, sacroiliac joint compression would be expected

to aggravate osteoarthritic changes, whereas joint distraction would be expected to stress any injured or inflamed sacroiliac ligaments.

A variation of this basic technique uses repeatedly applied laterally directed forces over the ischial tuberosity instead of the tuber sacrale (see Figure 51-7). This procedure incorporates two long lever arms to stress the supporting sacroiliac ligaments. Again caution should be taken not to apply excessive force because of the long lever arm action of the sacral apex and ischial tuberosities on the sacroiliac ligaments. Lastly, proximal hindlimb manipulation is done to assess coxofemoral and stifle joint range of motion and the willingness to actively extend the hindlimb. Concurrent joint stiffness or muscle hypertonicity can be identified and localized as the proximal aspect of the hindlimb is passively protracted, abducted, flexed, and retracted.

LOCAL ANALGESIA

Intraarticular analgesia of the sacroiliac joint is nearly impossible because of its deep anatomical location and inaccessible joint capsule.³⁴ Experimentally, intraarticular sacroiliac injections have been accomplished by drilling a hole through the wing of the ilium, dorsal to the sacroiliac joint.¹⁸ Regional perfusion with local anesthetic solutions or antiinflammatory drugs for diagnostic or therapeutic purposes was described.³⁵ Approaches from the cranial aspect of the wing of the ilium and the lumbosacral junction are typically used³²; however, because of the wide overlying wing of the ilium, the proximity and diffusion of the medication near the sacroiliac joint are questionable.

I recommend a caudomedial approach to the sacroiliac joint region because of anatomical and pathological considerations.³⁴ The caudomedial portion of the sacroiliac joint is the most frequent site of pathological conditions of the sacroiliac joint.^{1,4,17} Therefore diagnostic analgesia or therapeutic analgesia or antiinflammatory drugs should be directed toward the caudal aspect of the sacroiliac joint in the region of documented pathological condition. Two approaches are described, using 20- to 25-cm-long needles, depending on the depth and conformation of the gluteal musculature (Figure 51-8). Surgical preparation of the injection site is recommended, similar to other joint injection techniques. Ultrasound guidance is also recommended to allow the caudomedial aspect of the sacroiliac joint to be seen and identification of neurovascular structures that must be avoided at the greater sciatic foramen (see Figure 51-2).^{34,35} The cranial gluteal artery and nerve emerge laterally around the caudal margin of the ilial wing and travel dorsocaudally, adjacent to the sacroiliac joint. Other vital structures, including the sciatic nerve, lie ventral to the sacroiliac joint and travel on or within the substance of the sacrosciatic ligament.

The first approach involves needle placement dorsally over the iliac wing, ipsilateral to the affected sacroiliac joint (see Figure 51-8, A). This approach is technically easier, but it potentially has a higher risk of injury to the adjacent neurovascular structures. The needle is directed ventrally, toward the region of the sacroiliac joint, and walked off the caudal border of the iliac wing in the region of the sacroiliac joint. Care must be taken to avoid the deeper neurovascular structures. The needle is not advanced once it is walked off the caudal aspect of the iliac wing.

Figure 51-8 • Diagram of two approaches to the sacroiliac joint for diagnostic analgesia and therapeutic analgesia or administration of antiinflammatory drugs (dorsal view). **A**, Dorsal approach over the ipsilateral iliac wing near the caudomedial aspect of the affected sacroiliac joint. **B**, Medial approach from the cranial aspect of the contralateral tuber sacrale with the needle directed toward the caudomedial aspect of the affected sacroiliac joint.

Diffusion of the injected material occurs within the middle or accessory gluteal muscles, near the caudomedial attachments of the ventral sacroiliac ligament.

A second preferred approach involves needle placement at the cranial margin of the contralateral tuber sacrale (see Figure 51-8, B). This approach is slightly more technically challenging but has a lower risk of injury to the adjacent neurovascular structures. The needle is inserted along the cranial aspect of the contralateral tuber sacrale and directed toward the cranial edge of the ipsilateral greater trochanter. The needle is placed contralaterally to the affected sacroiliac joint because the needle has to be guided between the divergent sixth lumbar and first sacral dorsal spinous processes and directed into the space formed by the ventral aspect of the ilial wing and the dorsal portion of the sacrum. The needle is advanced caudolaterally along the medial aspect of the affected ilial wing toward the caudomedial portion of the affected sacroiliac joint until contact is made with bone, near the sacroiliac joint margin. Diffusion of the injected material is expected to occur within the longissimus muscle or interosseous sacroiliac ligament. The dorsal nerve branches of the sacral nerves possibly may also be affected with this approach because the nerves exit the first and second dorsal sacral foramina.

DIAGNOSTIC IMAGING

Ultrasonography has been used to evaluate the dorsal surface of the iliac wing and caudal margin of the sacroiliac articulation to identify dorsal cortex irregularities associated with incomplete and complete ilial wing fractures.^{36,37} The dorsal sacroiliac ligament can be readily imaged on either side of the sacral dorsal spinous processes caudal to the tubera sacrale.⁹ Abnormal ultrasound images of the dorsal sacroiliac ligament include enthesopathies at the

tubera sacrale attachment sites, hypoechoic changes within the ligament, and modification of fiber orientation.^{9,22,38} Increased cross-sectional area of the dorsal sacroiliac ligament was reported to cause acute lameness, whereas decreased cross-sectional area was observed in horses with chronic lameness associated with sacroiliac injuries.³⁸ The thoracolumbar longissimus fascia and tendon lie medial to the dorsal portion of the dorsal sacroiliac ligament and blend with its fibers as it inserts on the sacral spinous processes.¹⁰ Longissimus tendonitis needs to be differentiated from dorsal sacroiliac desmitis because management of the two conditions may vary considerably.³⁹ The interosseous sacroiliac ligament has not been imaged because of its inaccessible location underneath the ventral aspect of the ilial wing. In contrast, the ventral sacroiliac ligament and the ventral joint margins of the sacroiliac joint can be seen using transrectal ultrasonography.⁹ Ventral periarticular modeling of the sacroiliac joint was observed with transrectal ultrasound approaches.³⁹

Primary indications for radiography of the pelvis include acute or severe pelvic asymmetries, upper hindlimb lameness, and pelvic crepitus or fractures.⁴⁰ The deep anatomical location of the sacroiliac joint and superimposition of abdominal viscera make radiographic imaging difficult at best. Ventilation-induced blurring of the abdominal viscera during general anesthesia with horses in dorsal recumbency is a simple technique to help delineate the bony structures of the sacroiliac region.⁴¹ The radiological features of chronic sacroiliac joint disease are minimal and include nonspecific increases in the joint space and enlargement of the caudomedial aspect of the sacroiliac joint.⁴ Radiography is not a sensitive indicator of sacroiliac joint disease because presumably normal horses may have dramatic differences in sacroiliac joint shape.⁴¹ Linear tomography was used to examine the lumbosacral and sacroiliac regions of horses, but limited access to equipment has restricted its clinical usefulness.¹⁵ Positive findings include widening of the sacroiliac joint and irregular joint outlines, with osteophyte formation at the caudal aspect of the joint. Osseous changes are common bilaterally, but they may be more pronounced on the clinically more affected side.¹⁵

Nuclear scintigraphy is considered by some authors to be an accurate and diagnostically useful technique for identifying acute and chronic sacroiliac joint injuries. However, ilial wing and soft tissue attenuation (from 71% to 82%), large distance between the ilial wing and camera face, horse movement, and background activity severely compromise the pelvic scintigraphic image, and only dramatic radiopharmaceutical uptake (RU) can be reliably detected.^{42,43} In addition, large variations exist in RU in both affected and unaffected horses. Young horses have well-defined tubera sacrale and relatively less RU in the adjacent regions of the sacroiliac joints.⁴⁴ Older horses and horses with sacroiliac joint pathology have less distinct differences in RU between the tubera sacrale and the sacroiliac joints.¹⁹ Subjective evaluation or quantitative analysis of bone scans typically is able to identify asymmetric RU over the affected tuber sacrale or wing of the ilium in the region of the sacroiliac joint. However, presumed normal horses, without a history of hindlimb or sacroiliac joint injuries, may have mild asymmetric RU over the tubera sacrale and sacroiliac joint regions.¹⁹ Non-motion-corrected scintigraphic images are

often not of diagnostic quality and can be misinterpreted as abnormal.⁴⁴ Motion-corrected images are much more likely to give accurate diagnostic information. A dorsal image of the sacrum is considered the most diagnostic image for evaluating and comparing the sacroiliac joints.¹⁸ However, RU in the relatively superficial tubera sacrale may mask RU in the sacroiliac joints in a dorsal image. Oblique images of the ilial wings are recommended to confirm left to right asymmetries in RU, especially when identifying stress fractures, and to separate the tuber sacrale dorsally from the sacroiliac joint region ventrally.⁴⁵ However, oblique images may be difficult to interpret because of inconsistent camera positioning on the left and right sides. The thick overlying gluteal musculature may also attenuate RU from an affected sacroiliac joint.⁴³ Any left-right asymmetry in gluteal muscle mass will produce a false-positive interpretation of RU on the side with the atrophic or reduced muscle mass.⁴² Stress fractures of the ilial wing may be difficult to differentiate from sacroiliac joint injuries because of the common location and extension of the incomplete fracture line into the sacroiliac joint.^{18,27,46} Increased RU (IRU) within the pelvis does not necessarily indicate a primary cause of pain.⁴⁷ A compensatory response within the osseous pelvis, insufficient pelvic pain to cause lameness, and other sources of lameness that cause more discomfort than the pelvic lesion associated with the area of IRU may all cause disassociation between a positive scintigraphic finding and the primary source of pain. Nuclear scintigraphy should also include the caudal thoracolumbar spine to rule out concurrent pathology, such as impinging dorsal spinous processes.¹⁹

Thermography is used to diagnose muscle strain or inflammation in the sacroiliac and croup regions. Horses with sacroiliac joint injuries are expected to have protective muscle spasms in the adjacent musculature. Palpation of muscle sensitivity has been correlated with abnormal thermographic images in most horses.⁴⁸ Thermographic imaging of horses with sacroiliac injuries demonstrates a change in the normal temperature pattern over the croup, with increased temperature associated with acute desmitis and decreased temperature over the sacroiliac area on the affected side in horses with chronic sacroiliac injury.³⁸ In the Editors' experience thermography may be helpful in the identification of acute desmitis of the dorsal sacroiliac ligament, but is usually of no value in the assessment of horses with chronic sacroiliac joint region pain. All diagnostic imaging modalities need to be carefully evaluated with respect to clinical signs exhibited by the individual horse.^{19,49}

DIFFERENTIAL DIAGNOSIS

Causes of sacroiliac joint pain or injury were postulated to result from sacroiliac or lumbosacral arthrosis, sacroiliac desmitis or sprain, sacroiliac subluxation or luxation, pelvic stress fractures, complete ilial wing fractures, or sacral fractures.³² Additional differential diagnoses include aortoiliac thromboembolism, exertional rhabdomyolysis, trochanteric bursitis, and impinged dorsal spinous processes in the lumbar vertebrae.²⁵ Horses with presumed thoracolumbar vertebral problems may also have concurrent chronic sacroiliac joint injuries. In a report on 443 horses with back problems, chronic sacroiliac joint problems were identified

in 15%.¹¹ Clinical signs of lower hindlimb lameness may overlap and mimic signs of presumed pathological conditions of the sacroiliac joint. It is important that a thorough and complete lower limb lameness evaluation is completed before, or along with, an upper hindlimb or sacroiliac joint workup.

Based on a review of the literature, OA of the sacroiliac joint is the most prevalent disease process affecting horses with sacroiliac joint pain or dysfunction.^{1,4,11,17} Sacroiliac desmitis was documented in horses and may be an important cause of pathological conditions in horses with acute sacroiliac joint injuries.⁹ Documented complete rupture of the sacroiliac ligaments was only reported in a few horses with acute and chronic disease.^{17,24} The presumed diagnosis of sacroiliac joint subluxation based solely on tubera sacrale height asymmetry is inappropriate.³¹ Horses with chronic sacroiliac problems and presumed sacroiliac joint subluxation have not had identifiable changes in the sacroiliac ligaments at necropsy.⁴ In addition, STB trotters with substantial tubera sacrale height asymmetries did not have significant increases in sacroiliac pain compared with horses with lesser degrees of asymmetry.¹⁶ In my opinion, an antemortem diagnosis of sacroiliac joint luxation can only be supported if an acute change in tubera sacrale height caused by substantial trauma has been documented or if sacroiliac joint instability (i.e., crepitus or independent tubera sacrale movement) is evident during physical examination. Pelvic stress fractures should be ruled out in horses with sacroiliac pain or dysfunction.⁵⁰ A high prevalence of occult pelvic stress fractures was reported in TB racehorses.⁴⁶ The incomplete fracture lines extend into the caudomedial aspect of the sacroiliac joint, which could possibly produce concurrent sacroiliac joint inflammation and OA. A diagnosis of sacroiliac joint injury is often based on a diagnosis of exclusion because of difficulties in clinical evaluation and diagnostic imaging. We are hopeful future investigations into sacroiliac joint problems in horses will produce a better and more comprehensive understanding of this often misdiagnosed clinical entity.

TREATMENT

Because definitive diagnosis of pathological conditions of the sacroiliac joint is difficult, treatment recommendations are usually symptomatic. Few studies on treatment efficacy have been reported in the equine literature. In people, analgesics, antiinflammatories, intraarticular and periarticular injections of corticosteroids, and prolotherapy (i.e., injection of sclerosing agents) were advocated as sole treatments for sacroiliac joint dysfunction. However, effective treatment and long-term rehabilitation of sacroiliac joint injuries often rely on the development of specific physical therapy and training programs that stimulate neuromotor and biomechanical restoration of articular, muscular, fascial, and ligamentous function.³⁰ In general, rest and various forms of physical therapy are indicated for horses

with ligamentous injuries. Prolonged rest (6 to 12 months) and systemic antiinflammatory medications are prescribed for horses with acute and chronic sacroiliac joint injuries. Complete box stall rest for 30 to 45 days was recommended to support ligamentous healing in horses with acute injuries.²⁵ The local injection of irritants or sclerosing agents was suggested to stimulate fibrosis and subsequent sacroiliac joint stability.²⁵ In my opinion, no scientific support or clinical indication exists for such proposed treatments of back or sacroiliac joint problems. With such haphazard and potentially injurious treatment modalities there appears to be a better chance of inducing further injury rather than of stimulating any healing response. Treatment of horses with chronic sacroiliac joint injury typically focuses on a gradual return to a low level of exercise to maintain muscle development of the back and gluteal regions to counteract the clinical signs of poor performance and reduced hindlimb impulsion.²⁹ Extended rest is contraindicated because reduced muscle tone may exacerbate the injury.

Because of the deep and inaccessible location of the sacroiliac joint, intraarticular injections of local anesthetic solutions or antiinflammatory medications for diagnostic or therapeutic purposes are impractical.¹⁸ However, local perfusion of the sacroiliac joint with local anesthetic solutions or antiinflammatory drugs for diagnostic and therapeutic purposes is a viable alternative.³² Concurrent lameness of the ipsilateral lower hindlimb was reported in horses with signs of chronic sacroiliac joint injuries.¹⁸ Therefore a detailed lameness examination coupled with appropriate treatment of the pathological conditions of the lower hindlimb is often indicated. Additional factors such as corrective shoeing and modifications in exercise or training programs need to be addressed concurrently. Acupuncture and chiropractic are nontraditional approaches that are used by some clinicians to assist in the diagnosis and symptomatic treatment of horses with presumed sacroiliac joint problems. Efficacy of modalities needs to be confirmed before further recommendations can be made.

PROGNOSIS

Long-term follow-up evaluation suggests that prognosis for horses with sacroiliac joint injury is poor for return to the previous level of activity.¹⁸ Some horses may have an improvement in performance or lameness but will not be able to return to normal athletic activities because of recurring, low-grade lameness. Most horses will be pasture sound or able to function only at low levels of exercise. We hope that improvements in providing a specific diagnosis of the type of sacroiliac joint injury present will provide affected horses with better and more specific treatment options in the future.

Chapter 52

Thoracolumbar Spine

Jean-Marie Denoix and Sue J. Dyson

Back problems are a major cause of altered gait or performance (see Chapters 50, 51, and 97). Both identification and documentation of vertebral lesions are difficult in horses; therefore treating back pain is a challenge for the equine clinician. The equine back is a large area covered by thick muscles. Therefore assessment of the bony elements is limited. Every joint in the thoracolumbar region has restricted mobility; therefore detecting changes in restricted movement when the horse is working is difficult. Diagnostic imaging of the thoracolumbar region is also limited, and radiological assessment requires special equipment. Specific treatment of back pain can only be performed after complete identification of the site and nature of the lesions.

ANATOMY AND FUNCTION

Bones

The thoracolumbar spine is basically composed of 18 thoracic vertebrae (T1 to T18), six lumbar vertebrae (L1 to L6), and five fused sacral vertebrae (S1 to S5). Some horses have individual (congenital) variations at the cervicothoracic, thoracolumbar, and lumbosacral junctions. The most common is the sacralization of the last lumbar vertebra (sacralization of L6), which can be seen by ultrasonography. Transitional vertebrae, with a rib on one side and a transverse process on the other side, can be found at the thoracolumbar junction. Intervertebral ankylosis alters the biomechanical behavior of the involved part of the spine, especially at the lumbosacral junction, which in normal horses is the most mobile joint between T2 and S1. Ankylosis of this joint puts more stresses on the caudal lumbar intervertebral joints and may predispose to osteoarthritis (OA) of the facet joints and intervertebral disk lesions. Fusion of the lumbar transverse processes (see the following discussion) is also sometimes seen, and this has similar consequences on adjacent intervertebral joints, but the consequences are fewer because little movement usually occurs in these joints. Transitional transverse processes, or ribs that do not involve the vertebral body, have less biomechanical significance.

The first 10 thoracic vertebrae have long spinous processes. These have a dorsocaudal orientation and provide insertion for the strong but elastic supraspinous ligament. The anticlinal vertebra, the vertebra with a spinous process perpendicular to the vertebral axis, is usually T15. Caudal to the anticlinal vertebra the spinous processes are orientated obliquely dorsocranially. The spinous processes are higher between L2 and L5. Therefore lumbar muscular atrophy results in a kyphotic appearance of the lumbar area.

In most horses the spinous processes of L6 and S1 are divergent, allowing a range of flexion and extension

movements at the lumbosacral joint. The transverse processes from L5 (sometimes L4) to S1 articulate through intertransverse synovial joints, which limit lateral flexion in this area. The lumbar vertebral bodies are bigger than the thoracic ones and have a ventral crest for the insertion of the diaphragm.

Joints

Stability of the thoracolumbar vertebrae is provided by the supraspinous and interspinous ligaments, the joints between the cranial and caudal articular processes (the facet joints), the joints between the vertebral bodies, and the dorsal and ventral longitudinal ligaments. Stability of the spinous processes is provided by the supraspinous and interspinous ligaments (Figure 52-1). These ligaments are wider and more elastic in the cranial and middle thoracic areas, permitting more movement than in the caudal thoracic and lumbar regions.

The caudal and cranial articular processes articulate via synovial intervertebral articulations (the facet joints). At the base of the spinous processes these joints are symmetrically placed on each side of the median plane (Figure 52-2). These are typical synovial (diarthrodial) joints with articular cartilage, a closed synovial cavity containing synovial fluid, a synovial membrane, and a fibrous capsule. They have a single flat articular facet in the cranial thoracic area (up to T12) and two angulated articular facets between T12 and T16. From T17 to S1 the articular facets are congruent,

Fig. 52-1 • Anatomical specimen showing the ligaments of the thoracolumbar spine. Cranial is to the right. 1, Supraspinous ligament; 2, interspinous ligament; 3, ventral longitudinal ligament; 4, fibrous superficial part of the intervertebral disk; 5, articular capsule of the synovial intervertebral joint; 6, first lumbar vertebra; 7, third lumbar vertebra.

Fig. 52-2 • Anatomical specimen showing a synovial intervertebral articulation. 1, Caudal articular process; 2, cranial articular process; 3, joint space; 4, articular margin; 5, articular capsule and synovial membrane (reflected); 6, first lumbar vertebra; 7, second lumbar vertebra.

with a cylindrical shape aligned on a paramedian axis. These regional variations are correlated with the limited mobility of the lumbar spine and the wider range of movement in the thoracic region, including flexion and extension in the median plane, lateral flexion in the horizontal plane, and rotation. The vertebral bodies are stabilized by joints composed of a fibrous intervertebral disk and two longitudinal ligaments. The ventral longitudinal ligament is replaced by the longissimus cervicis muscle in the cranial thoracic area. The dorsal longitudinal ligament is located in the vertebral canal and adherent to the dorsal border of each intervertebral disk.

Muscles

The vertebral column is moved by wide muscles (Figure 52-3). The strong epaxial muscles, located dorsal to the vertebral axis, have an extensor effect when contracted bilaterally. Unilateral contraction induces lateral flexion and contributes to rotation of the vertebral column. Electromyographic studies show that the epaxial muscles limit flexion and stabilize the vertebral column during the suspension phase at the trot.^{1,2}

The epaxial muscles include the following:

1. Spinosus muscle, inserting on the spinous processes
2. Longissimus dorsi muscle, which extends to the caudal cervical spine
3. Iliocostalis muscle

The longissimus dorsi is the strongest muscle. The iliocostalis muscles are small but have a greater role in lateral flexion because of their eccentric location. Caudally, these muscles fuse to form the erector spinae muscle. The multifidus muscle lies under the spinosus muscle and is in close contact with the vertebrae (juxtavertebral muscle). This muscle plays a major role in the stability of the vertebrae and in the proprioceptive adjustment of the spine.

Fig. 52-3 • Transverse anatomical section of the normal lumbar region of a 6-year-old Selle Français mare. 1, Vertebral head of third lumbar vertebra; 2, cranial articular process of third lumbar vertebra; 3, caudal articular process of second lumbar vertebra; 4, multifidus muscle; 5, erector spinae muscle; 6, psoas muscles; 7, supraspinous ligament; 8, ventral longitudinal ligament.

The hypaxial muscles, located ventral to the vertebral axis, have a flexor effect on the spine when contracted bilaterally. Unilateral contraction induces lateral flexion and contributes to rotation of the vertebral column. The hypaxial muscles include psoas minor and major, rectus abdominis, and rectus oblique.

The psoas minor and major muscles insert on the ventral aspect of the lumbar and caudal three thoracic vertebrae (juxtavertebral muscles). They act mainly at the lumbosacral junction but are also able to flex the thoracolumbar junction and the lumbar spine. The rectus abdominis muscle is an effective flexor of the complete thoracolumbar spine because of its eccentric insertions on the pubis, sternum, and ventral part of the ribs. The oblique muscles can create lateral flexion and rotation of the thoracolumbar spine because of eccentric insertions on the tubera coxae and ribs. Electromyographic studies show that the rectus abdominis muscles act to limit extension and stabilize the vertebral column during each diagonal stance phase at the trot.^{1,2}

Blood Vessels and Nerves

The vertebrae, intervertebral joints, and axial muscles are supplied by segmental thoracic and lumbar arteries and veins. Innervation is provided by thoracic and lumbar spinal nerves that pass through the intervertebral foramina.

DIAGNOSIS OF BACK PAIN

The objectives of clinical examination of the horse's back³⁻⁷ are to determine whether back pain is present, the site or sites of pain, and the potential lesions responsible for the pain. Acute back pain can arise after traumatic injuries, such as a fall, or after an awkward jump. Acute pain and muscle spasm may be identified and may be the primary lesion, but a complete radiographic examination of the thoracolumbar spine may be indicated to assess for

vertebral fractures or long-standing bony lesions that may be responsible for the accident. These lesions may become clinically significant because of overstress on the intervertebral structures. For example, a long-standing spondylosis lesion may cause acute pain on landing after a jump.

A poor rider or an ill-fitting saddle may cause back pain, but correction of these problems may not be easy. It is important to manage these causes of back pain before proceeding with more advanced imaging techniques.

Back pain may also be manifest by abnormal behavior, for example, bucking (see page 992).

Physical Examination

Physical examination is essential in diagnosing back pain. Only the main criteria for each step or procedure are discussed. It is obviously important to perform a comprehensive evaluation of the whole horse to identify any other potential problems that may contribute to gait abnormalities or poor performance.

Inspection

The most commonly described abnormal curvatures of the back are lumbar kyphosis and thoracic lordosis. These can be seen in the same horse. Atrophy of the epaxial muscles in the lumbosacral regions results in prominence of the normal summits of the spinous processes and apparent kyphosis of the lumbar spine. Detection of atrophy of the epaxial muscles is a key finding in a horse with potential back pain because atrophy reflects the reduction of movement in the painful areas. The finding can help provide information on the possible location of the lesions. However, one should bear in mind that muscular development also reflects the horse's previous work history, and if the horse has never worked properly through its back, the epaxial muscles will be poorly developed.

Thoracic lordosis may be seen in clinically normal horses and does not necessarily imply the presence of back pain. However, a short coupled horse with lordosis is more likely to have impinging spinous processes, a reflection of the horse's normal conformation.

Abnormal swellings in the saddle area or abnormal hair loss may reflect a poorly fitting saddle or the position and balance of the rider. A rider who sits crookedly predisposes to excessive movement of the saddle and asymmetrical hair loss. However, it should be noted that hindlimb lameness may also induce abnormal movement of the saddle.

The stance of the horse may also be important; some horses with back pain may stand either camped out or camped under. However, a normal stance certainly does not preclude thoracolumbar region pain.

Palpation

Palpation of the thoracolumbar region should be performed with the horse standing quietly, bearing weight evenly on all limbs. Time should be spent getting the horse accustomed to the clinician's presence, especially with an apprehensive horse, so that the horse's true reactions to pain and pressure can be assessed. Unless approached quietly a thin-skinned Thoroughbred (TB) type may give a false impression of guarding the back and having protective spasm of the epaxial muscles.

Palpation of the superficial structures of the thoracolumbar region helps to identify supraspinous desmopathy

and deformation or malalignment of the spinous processes. Identification of localized muscle tension can be a key feature in establishing the presence of a clinically significant lesion. The thickness of the epaxial muscles prohibits accurate assessment of deeper structures.

Pressure

Pressure on the superficial structures, such as the supraspinous ligament and the epaxial muscles, is useful to assess pain. Reliably assessing the response to pressure applied to deeper structures, such as the epaxial synovial intervertebral articulation complexes, is not possible.

Mobilization

Stimulation of movement of the thoracolumbar spine (Figure 52-4) is important to assess the amount of movement tolerated by the horse and any signs of pain, such as flexion of the limbs, alteration of facial expression, tension of the back muscles, movement of the tail, and alteration of behavior (kicking, rearing, bucking, and grunting).

The following protocol is recommended:

1. Assessment of thoracic flexion, thoracic extension, thoracolumbar extension, lumbosacral extension, and complete thoracolumbar and lumbosacral flexion in the median (sagittal) plane

Fig. 52-4 • Physical examination by left lateral flexion of the thoracolumbar spine. The two main criteria evaluated are the amount of movement and manifestations of pain.

2. Assessment of right and left thoracolumbar lateral flexion (and rotation) (see [Figure 52-4](#))
3. Assessment of left and right cervical (and thoracic) lateral flexion (and rotation)

The clinician should try to determine which movements are restricted or not tolerated so as to determine potential sources of pain. These movements can be induced by skin stimulation of the dorsal and lateral aspects of the trunk and hindquarters. Although some horses respond to soft digital stimulation, in others a stronger stimulus is required, for example, using the tips of a pair of artery forceps. Firm stroking with a hard instrument displaced craniocaudally and inducing spectacular wide extension and flexion movements may lack sensitivity and specificity in determining the site of back pain, but firm stroking may be necessary in extremely stoical cob-type horses to induce any movement. A normal, relaxed horse is able to flex and extend the thoracolumbar spine smoothly and repeatedly. The degree of movement reflects in part the type of horse. Cob-type horses naturally tend to have much more restricted movement than TBs or Warmbloods. The clinician will find it useful to keep one hand resting on the midback region during these maneuvers to detect induced muscle spasm or abnormal cracking of the muscles or ligaments (a crepitus-like feeling as the epaxial muscles or ligaments contract and relax). Further descriptions of assessment of thoracolumbar movement are provided in Chapter 51. Pressure algometry has been used to more objectively quantify back pain.^{8,9}

Examination during Movement

Evaluation of the horse moving at walk, trot, and canter is essential to assess whether pain is present and to identify functional disorders, such as limitation of regional intervertebral mobility ([Figure 52-5](#)). The clinician should always bear in mind that impinging spinous processes can

be present asymptotically. Therefore the clinical significance of impinging spinous processes should not be overinterpreted, unless clinical signs of back pain are evident. The horse should be assessed moving in straight lines and in small circles at a walk and trot on a hard surface and moving at a trot and canter on the lunge to determine whether any reduction of back mobility is apparent ([Table 52-1](#)).

In vivo kinematic studies have quantified dorsoventral flexibility of the back in sound horses trotting^{10,11} and at various gaits on the treadmill.¹² Horses with vertebral lesions showed a reduction of passive flexibility of the

Fig. 52-5 • Dynamic examination by evaluating the active back movement at the canter on the lunge.

TABLE 52-1

<i>Criteria Used for Evaluating Back Disorders*</i>			
GROUND	GAIT	DIRECTION OF MOVEMENT	CRITERIA
Hard	Walk	Straight line	Rotation (tuber coxae mobility) (lateral flexion)
		Figure eight (3-m diameter)	Lateral flexion
	Trot	Left circle (7-m diameter)	Lateral flexion
Soft		Right circle (7-m diameter)	(Passive TL flexibility)
	Trot	Right circle (10-m diameter)	Passive DV flexibility (TL>LS)
			Lateral flexion
			Hindlimb propulsion
	Canter	Right circle (10-m diameter)	Active flexion and extension movements (LS>TL)
Hard			Hindlimb protraction/propulsion
			Hindlimb placement (rotary canter)
			Coordination and balance
	Trot	Left circle (10-m diameter)	Same as above
	Canter		
Hard	Trot	Left circle (7-m diameter)	Lateral flexion
		Right circle (7-m diameter)	(Passive TL flexibility)
		Straight line	Passive DV flexibility (TL>LS): side aspect
			Rotation (tuber coxae mobility); lateral flexion: caudal aspect

TL, Thoracolumbar; LS, lumbosacral; DV, dorsoventral.

*Assessment involves a horse moving first on a hard surface, then on a soft surface, and then on a hard surface, in straight lines and circles, at walk, trot, and canter.

back at trot,¹³⁻¹⁵ with reduced flexion and extension, lateral flexion, and rotation. Thus the horse may appear to hold its back rather stiffly. This can be caused by mechanical problems (partial or complete ankylosis) or pain. Back pain may also influence stride length and limb flight, resulting in a more restricted and less animated gait. On the lunge the horse may show loss of balance and a tendency to lean the body rather than bend the trunk toward the direction of circle. However, such clinical signs may also be seen in association with lameness, which, if bilateral, may not be obvious.

Examination of the Horse Being Ridden or in Harness

The presence and the degree of back pain may be underestimated unless the horse is evaluated under its normal working conditions, that is, ridden or in harness. The influence of a rider on mobility of the horse's back has recently been quantified.¹⁶ The clinician should watch carefully as the tack or harness is applied, particularly as the girth is tightened. However, the clinician should bear in mind that cold-back behavior (see Chapter 97) is not necessarily a reflection of back pain, although it may be. The fit of the saddle for the horse and the rider should be evaluated. Back mobility,³ the movements that the horse finds difficult, and the horse's attitude toward work should all be assessed (see Chapter 97). The clinician should pay attention also to the observations of the rider because the horse may feel considerably worse than it appears. The rider may describe lack of hindlimb power, lateral stiffness of the back to the left or right, unwillingness of the horse properly to take the bit, or loss of fluidity in the paces. The rider may complain of back pain induced by riding the horse.

Examination of the horse while it is ridden also gives the clinician the opportunity to assess the rider because back pain is readily induced by poor riding, a situation that may not be easy to handle diplomatically.

Local Analgesia

Diagnostic infiltration of local anesthetic solution may be useful to assess the clinical significance of impingement of spinous processes, where only the bones, ligaments, and adjacent muscles are affected by the analgesia. If impingement is severe, local anesthetic solution can only be deposited around the spinous processes and not between them. The volume of local anesthetic solution required depends on the number of spinous processes involved. Sixty to 80 mL of mepivacaine is injected at several sites using 4-cm needles if four or five impinging spinous processes exist. The response is assessed in 15 to 20 minutes and is most accurately evaluated by observing the horse while it is ridden and by the rider's feel. If kissing spines is the only clinically significant lesion, then substantial improvement should be anticipated, but if other lesions are contributing to pain, the response is limited.

If deeper injections are performed in the region of the epaxial synovial intervertebral articulations, interpretation may be confounded because the injections are effectively intramuscular injections, and the local anesthetic solution may readily diffuse to affect sites on the dorsal and ventral rami of the spinal nerves. Thus local analgesia

has potentially limited value for the assessment of the clinical significance of OA of the synovial intervertebral articulations and little value for assessment of intervertebral disk disease and spondylosis.

IMAGING

Radiography and ultrasonography are essential to determine potential causes of pain or mechanical restriction. Nuclear scintigraphy is also a useful tool to detect abnormal bone activity and to help establish the clinical significance of radiological findings.

Radiography

Indications for radiographic examination of the thoracolumbar spine include owner complaints of a back problem in their horse, abnormal clinical findings, poor performance, or as part of the assessment of an obscure lameness.

The horse should stand squarely on all limbs.¹⁷ Sedation may be necessary using detomidine (3 to 7 mg) or romifidine (12 to 25 mg). A high-output x-ray machine is necessary, with a rotating anode and an 80-kW power generator, for example.

Imaging plates or cassettes (20- × 40-cm format) with fast screens and sensitive or high-sensitive films are used to provide highly sensitive film-screen combinations. The cassettes should be placed in a vertically orientated ceiling or wall-mounted cassette holder, which can be aligned with the x-ray machine. The cassette should be placed as close to the trunk of the horse as possible. A 10:1 ratio focused grid is used to reduce radiation scatter. The focus-film distance varies between 1.15 and 1.30 m. The x-ray beam is directed perpendicular to the vertebral column axis. At least five exposures are required (Figure 52-6) to obtain a complete evaluation of the thoracolumbar spine between T10 and L4. In some horses L5 or L6 may also be imaged. The exposure parameters are summarized in Table 52-2. Additional horizontal 20° ventral oblique radiographic images are useful to assess the left and right thoracic synovial intervertebral articulations.⁶ To reduce motion, the exposure is performed during the last part of expiration.

Ultrasonography

Ultrasonographic examination of all the epaxial structures is possible.¹⁸⁻²⁰ Imaging of the spinous processes and associated ligaments is performed with 7.5- or 10-MHz probes. A standoff pad is used to improve detection of the superficial structures. Imaging of the articular and transverse processes can be performed with 5- to 2.5-MHz probes. Longitudinal median and paramedian scans and transverse scans are combined to image all dorsal vertebral structures. For ultrasonographic examination the hair on the median plane over the spinous processes is removed with a No. 40 clipper blade, and the skin is cleaned. The skin is never shaved. When the hair is short (during the summer time), wetting the hair and skin with hot water for several minutes allows examination without clipping. Aqueous contact transmission gel is applied to the wet skin to couple the transducer to the skin to avoid air interference and artifacts. The lumbosacral and intertransverse lumbar and lumbosacral articulations can be assessed per rectum.²¹

Fig. 52-6 • Position of the imaging plates for radiographic examination of the thoracolumbar spine. 1, Thoracic spinous processes; 2, lumbar spinous processes; 3, lumbar vertebral bodies and synovial intervertebral articulation; 4, thoracolumbar vertebral bodies and synovial intervertebral articulation; 5, thoracic vertebral bodies and synovial intervertebral articulation.

TABLE 52-2

Technical Parameters Used for the Exposure of Different Regions of the Thoracolumbar Spine*

REGIONS	FILM	KV	MA	EXPOSURE DURATION (MSEC)
Thoracic dorsal spinous processes	Sensitive	73-77	80-110	71-107
Lumbar dorsal spinous processes	Sensitive	77-83	110-160	110-182
Midthoracic region, vertebral bodies, and facet joints (T10-T16)	High sensitive	70-77	100-140	86.5-141
Thoracolumbar junction, vertebral bodies, and facet joints (T15-L2)	High sensitive	81-85	160-250	177-344
Lumbar region, vertebral bodies, and facet joints (T18-L4)	High sensitive	85-93	280-320	406-580

*All examinations performed using a 10:1 grid and rare earth fast screen. Horses of 450- to 650-kg body weight.

Nuclear Scintigraphy

Patterns of radiopharmaceutical uptake (RU) in clinically normal riding horses have been described and compared with radiological findings.^{22,23} In a retrospective study of 50 horses with back pain, the most common abnormal finding was increased radiopharmaceutical uptake (IRU) in the spinous processes between T12 and L2, identified in 48 horses.²⁴ Three horses had abnormal RU in the vertebral bodies of L3 to L6 and T11 to T14. Patterns of RU associated with OA of the synovial intervertebral articulations²⁵ and spondylosis²⁶ have been described. However, normal RU does not preclude the presence of clinically significant osseous pathology.^{25,26}

Lateral or slightly oblique lateral images give the most information. Scattered radiation is a problem because of the large muscle mass overlying the vertebrae, so use of a high-resolution collimator is preferred. This requires longer acquisition times to obtain an adequate number of counts to give adequate image quality. Slight swaying movement

of the horse during image acquisition and the movement of breathing detract from image quality unless motion correction software is used. The gamma camera may need to be angled slightly to avoid the kidneys being superimposed over the caudal thoracic vertebrae. At least three images are required to evaluate the entire length of the thoracolumbar spine, and comparable images from the left and right sides can be useful. If images are acquired from only one side, the right side is best because of the position of the kidney. Dorsal images are occasionally useful to clarify the anatomical position of a focus of IRU identified in a lateral image. The summits of the spinous processes in the withers region, the caudoproximal aspect of the scapula, and the kidneys may all have greater normal RU than the rest of the thoracolumbar spine and may effectively conceal lesions (Figure 52-7). Masking these areas out after image acquisition potentially results in more information. Using a high-frequency filter can also yield additional information, making a subtle focus of IRU more obvious, and

Fig. 52-7 • **A**, Motion-corrected scintigraphic image of the cranial thoracic vertebrae without a filter. There is greater radiopharmaceutical uptake (RU) in the summits of the spinous processes in the withers region and the scapula than elsewhere. **B**, The same image as **A** after masking the scapula. **C**, The same image as **A** after masking the summits of the spinous processes at the withers and the caudal aspect of the scapula. Masking increases the information available. These images show normal patterns of RU.

facilitating anatomical localization of IRU. Image resolution in fat horses may be compromised by scattered radiation in the soft tissues.

Thermography

Normal thermographic patterns of the thoracolumbar region have been described.²⁷ Thermography may be useful in identifying acute superficial muscle injuries or demonstrating to an owner the impact of a poorly fitting saddle or a rider sitting crookedly. However, in horses with chronic back pain, thermography does not usually add useful information and lacks sensitivity and specificity.

LESIONS

Spinal Processes and Associated Ligaments

Impingement of the Dorsal Spinous Processes: Kissing Spines and Overriding Spinous Processes

Impingement of the summits of the spinous processes, or kissing spines, is a well-known pathological entity of the horse's back²⁸; however, it is important to recognize that

lesions may not be restricted to the summits, and the entire length of the spinous processes must be evaluated. The most common location of these lesions is the vertebral segment between T10 and T18 (Figure 52-8), although lesions also occur between L1 and L6.¹⁷ Modeling of the dorsal aspect of a spinous process or an avulsion fracture reflects an insertional lesion of the supraspinous ligament. We grade impingement of the dorsal part of the spinous processes as follows:

- Grade 1: Narrowing of the interspinous space with mild increased opacity of the cortical margins of the spinous processes
- Grade 2: Loss of the interspinous space with moderate increased opacity of the cortical margins of the spinous processes
- Grade 3: Severe increased opacity of the cortical margins of the spinous processes, caused in part by transverse thickening, or radiolucent areas
- Grade 4: Severe increased opacity of the cortical margins, osteolysis, and change in shape of the spinous processes; overriding (overlap) of the spinous processes

Fig. 52-8 • Lateral radiographic image of the spinous processes of the twelfth to sixteenth thoracic vertebrae. Cranial is to the left. There are radiological signs of impingement of the spinous processes between the eleventh and sixteenth thoracic vertebrae, with clinically significant marginal bone remodeling. T14, Fourteenth thoracic vertebra.

Overriding of spinous processes is a congenital condition with abnormal orientation of the spinous processes and similar changes in the margins of adjacent spinous processes. Other congenital abnormalities include complete fusion of two adjacent spinous processes or “webs” of spinous processes, or bony bridges between one or more adjacent spinous processes. The contour of the middle part of a spinous process may be altered because of enthesophyte formation at the insertion of the interspinous ligaments. Kissing lesions may also be seen at the ventral part of a spinous process with type 4 lesions of the epaxial synovial intervertebral articulation (see page 601). Generally speaking, the more severe and extensive the radiological abnormalities, the more likely they are to be of clinical significance; however, two close spinous processes may be associated with pain in a horse with a low pain threshold.

Ultrasonographic examination can easily demonstrate contact or modeling between two adjacent spinous processes, transverse thickening of the processes, and abnormal alignment. However, ultrasonography is more useful to assess concomitant supraspinous ligament lesions, including insertion desmopathies (enthesopathies) on the summits of the spinous processes.

Nuclear scintigraphy can help identify evidence of active bone modeling of the spinous processes and other potential lesions. However, one must bear in mind that active bone modeling is not synonymous with pain. Increased modeling of the dorsal aspects of the spinous processes may reflect impingement or insertional desmopathy of the supraspinous ligament (Figure 52-9). The degree of IRU does not always appear to be well correlated with the severity of the clinical signs or the radiological abnormalities (see Figure 52-9, A). Obvious focal IRU can be seen in horses with neither back pain nor radiological abnormality, whereas some horses with back pain associated with impinging spinous processes have only mild IRU. Mechanical limitations may contribute to back stiffness, which may predispose to the development of other lesions.

Kissing spines can be found in performance horses with no clinical manifestations of back pain. Therefore the

Fig. 52-9 • **A**, Lateral nuclear scintigraphic image of the thoracolumbar region of a 10-year-old Grand Prix dressage horse with loss of action. There is increased radiopharmaceutical uptake (IRU) in the dorsal aspects of six adjacent spinous processes. The horse showed clinical signs of restricted mobility of the back. Radiographic examination revealed impinging spinous processes. The horse's gait was dramatically improved by infiltration of local anesthetic solution around the affected spinous processes. **B**, Lateral nuclear scintigraphic image of the thoracic region of an 8-year-old show jumper gelding with stiffness of the thoracolumbar region and poor hindlimb impulsion. A high-resolution filter has been applied to the image. There is mild IRU in the summits of two spinous processes in the caudal thoracic region (arrows). However, five adjacent spinous processes were impinging, and infiltration of local anesthetic solution produced a profound clinical improvement. No soft tissue lesions were identified by ultrasonography.

clinical significance of kissing spines must be carefully assessed. Kissing spines may also be present with another vertebral lesion, which may have a greater influence on prognosis; therefore a comprehensive evaluation of all structures should be performed, even if kissing spines have been identified. Radiological findings should be carefully correlated with the results of the physical examination and preferably with nuclear scintigraphic examination and the response to local analgesia.

Desmopathies: Supraspinous Ligament Injuries

Injuries of the supraspinous ligament occur most commonly between T15 and L3 and may be associated with palpable localized thickening and pain. Lesions are identified best by ultrasonography^{18,19}; however, it is important

to recognize that regions of altered echogenicity can be seen in some clinically normal horses.³⁰

Thickening of the supraspinous ligament induces a local deformation (bump) of the dorsal profile of the thoracolumbar area, which can be measured by ultrasonography and compared with two adjacent equivalent locations. Lesions usually occur at a spinous process, sometimes extending between two adjacent spinous processes. The normal supraspinous ligament is uniformly echogenic (Figure 52-10). Hypoechoic lesions in the deep and intermediate part of the supraspinous ligament (Figure 52-11) are compatible with recent or chronic desmopathies of the supraspinous ligament. Hyperechoic foci, with or without acoustic shadows, may be seen in the supraspinous ligament. They reflect chronic or old desmopathy. Insertion desmopathy (enthesopathy) of the supraspinous ligament can be identified by irregularity of the surface of the spinous process, with a thicker appearance. Alteration of echogenicity and fiber orientation occurs in the supraspinous ligament.

With low-exposure radiographs, the soft tissue thickening and some focal radiopacities may be seen in horses with long-standing injuries. Avulsion fractures or bone

modeling and increased opacity of the dorsal surface of the spinous processes may also be noted.²⁹

Nuclear scintigraphic examination may reveal IRU in the summit of one or more spinous processes in association with insertional lesions of the supraspinous ligament.

Fractures of Spinous Processes

Fractures of the spinous processes usually occur in the withers region as the result of the horse falling over backwards. However, other traumatic episodes, such as the horse getting stuck under a dividing rail between two compartments of a trailer or lorry (van), may result in fractures of more caudally located spinous processes. Fractures of the withers are often displaced, resulting in a change in conformation. There is generally focal pain and swelling, as well as marked back stiffness. An affected horse moves in a restricted fashion, often plaiting the forelimbs. Diagnosis is confirmed by radiographic or scintigraphic examination. Although the radiological abnormalities may be dramatic, the prognosis is generally favorable with conservative management. A purpose-fitted saddle may be required to accommodate the change in the horse's shape.

Articular Processes: Synovial Intervertebral Articulations

Normal Anatomy

The articular processes' synovial intervertebral articulation complex is located dorsal to the vertebral canal and is composed of the caudal articular process of one vertebra, the joint space, and the cranial articular process of the following vertebra (Figures 52-12 through 52-14).¹⁷

On lateral radiographic images, in the middle of the film, the left and right synovial intervertebral articulations are superimposed. On the extremities of the film, the images of the left and right synovial intervertebral articulations are progressively dissociated because of the divergent x-ray beam. In some horses the ribs are extremely convex dorsally and are superimposed over the thoracic and the first lumbar synovial intervertebral articulations, prohibiting assessment. Oblique radiographic images from left to right and right to left permit evaluation of the left and right synovial intervertebral articulations independently.⁶

Fig. 52-10 • Median (left) and transverse (right) ultrasonographic images of the normal supraspinous ligament in the lumbar area. 1, Skin; 2, supraspinous ligament; 3, second lumbar vertebra; 4, third lumbar vertebra; 5, interspinous ligament.

Fig. 52-11 • Transverse (left) and median (right) ultrasonographic images indicate supraspinous desmopathy. The ligament is thickened and presents a central hypoechoic zone (arrowheads). 1, Skin; 2, supraspinous ligament; 3, seventeenth thoracic spinous process.

Fig. 52-12 • Normal radiological appearance of the synovial intervertebral articulations in the midthoracic area. Cranial is to the left. T10, Tenth thoracic vertebra.

Fig. 52-13 • Normal radiological appearance of the synovial intervertebral articulations in the caudal thoracic area. Cranial is to the left. T14, Fourteenth thoracic vertebra.

Fig. 52-14 • Normal radiological appearance of the synovial intervertebral articulations in the lumbar area. Cranial is to the left. L2, Second lumbar vertebra.

The radiolucent cartilaginous joint space is thin and more clearly defined in the thoracic areas, where the articular facets are flat (see Figure 52-12), than in the lumbar area because of the condylar shape. Between T12 and T16 the joint space is a wide V shape, with a cranial oblique branch and a shorter vertical caudal branch (see Figure 52-13). At the thoracolumbar junction and in the lumbar region the joint space is less well defined. Usually, the joint space is linear and makes a 40-degree angle with the horizontal (see Figure 52-14). The caudal articular process is dorsal to the corresponding intervertebral foramen and is triangular with a caudal apex in the lumbar region. The thickness of the dense subchondral bone of the cranial articular process increases caudally. The cranial articular process is extended dorsocranially by a mammillary process, which is larger in the thoracic area than in the lumbar area.

On transverse ultrasonographic images obtained using 2.5- to 5-MHz probes, the synovial intervertebral articulations can be imaged (Figure 52-15). On each side the joint space separating the cranial (lateral) and caudal (medial) articular process can be identified.¹⁹ This joint space is limited dorsally by a thin articular capsule. Comparison of the left and right synovial intervertebral articulations of

Fig. 52-15 • Transverse ultrasonographic image of the synovial intervertebral articulations between the first and second lumbar vertebrae shows normal appearance (compare with Figure 52-3). 1, Caudal articular process of first lumbar vertebra; 2, cranial articular process of second lumbar vertebra; 3, transverse process of second lumbar vertebra; 4, multifidus muscle; 5, longissimus muscle; arrow, joint space of the epaxial synovial intervertebral articulation.

TABLE 52-3

Types of Radiographic Lesions of the Thoracolumbar Synovial Intervertebral Articulations

TYPES	GENERAL CRITERIA	RADIOLOGICAL SIGNS
1	Asymmetry	No clear joint space; double joint space
2	Modification of opacity of the articular process	Increased radiopacity of the subchondral bone Increased opacity of the synovial intervertebral articulations
3		Radiolucent areas in the subchondral bone Increased opacity of the articular process
4	Periarticular proliferation	Dorsal periarticular proliferation Increased size of the synovial intervertebral articulations Often associated with alteration in opacity of subchondral bone
5		Ventral periarticular proliferation
6	Ankylosis	Dorsal bridge between two adjacent vertebrae

the same intervertebral joint is helpful to assess size and shape.

Abnormal Findings

Eight types of abnormal radiological findings associated with OA have been identified in the synovial intervertebral articulations of the equine thoracolumbar spine^{6,17} (Table 52-3). These findings were mainly present at the

Fig. 52-16 • Lateral radiographic image of the thoracolumbar junction. Cranial is to the left. There are type 2 lesions (*arrows*) of the synovial intervertebral articulations between the eighteenth thoracic and first lumbar vertebrae in this 5-year-old French trotter male. Compare with the opacity of the cranial articular processes in [Figure 52-14](#). L1, First lumbar vertebra.

Fig. 52-17 • Lateral radiographic image of the cranial lumbar vertebrae. Cranial is to the left. There is a mild (grade 1) type 4 lesion of the synovial intervertebral articulation complex between the first (1) and second (2) lumbar vertebrae in this 8-year-old mare.

thoracolumbar junction and in the lumbar area. Types 2, 4, and 6 ([Figures 52-16 to 52-19](#)) were mainly found between T16 and L3. Types 5 and 7 have mainly been found in the lumbar area. However, lesions may occur anywhere from T9 to L5.⁶ Abnormalities have been found in mature riding horses and immature racehorses.

Dorsal periarticular proliferation (types 4 and 6) can be imaged with ultrasonography, and with this procedure determining whether the proliferation is symmetrical or, if not, which side is the most affected is possible ([Figure 52-20](#)).

Nuclear scintigraphy can be helpful in identifying evidence of abnormal bone modeling in the region of synovial intervertebral articulations, especially in horses where radiological appraisal is limited by the ribs. There was a strong association between the presence of moderate or intense IRU and radiological abnormalities in a study of 65 horses with back pain and radiological evidence of OA, whereas in 31 horses with no evidence of back pain RU was generally normal.²⁵

Fig. 52-18 • Bone specimen showing a moderate (grade 2) type 4 lesion (*arrowheads*) of the caudal articular process of the third lumbar vertebra. 1, Caudal articular process; 2, dorsal spinous process; 3, transverse process; 4, vertebral body; 5, vertebral fossa.

Fig. 52-19 • Lateral radiographic image of the midlumbar vertebrae. Cranial is to the left. There is a severe (grade 3) type 4 lesion (*arrowheads*) of the synovial intervertebral articulation between the third (3) and fourth (4) lumbar vertebrae in this 12-year-old mare.

In our experience, synovial intervertebral articulation lesions are much more consistently associated with back pain than are kissing spines. However, in a series of 644 horses with thoracolumbar region pain, only 77 (12%) had OA of the synovial intervertebral articulations, 47 of which had concurrent impinging or overriding dorsal spinous processes.⁶

Fig. 52-20 • Transverse ultrasonographic image of the synovial intervertebral articulation between the first and second lumbar vertebrae in a 5-year-old French trotter mare: on the left side (L) a dorsal periarticular osteophyte is present (arrowheads). 1, Caudal articular process of first lumbar vertebra; 2, cranial articular process of second lumbar vertebra; 3, transverse process of second lumbar vertebra.

Fig. 52-21 • Lateral radiographic image of the vertebral bodies of the caudal thoracic vertebrae. Cranial is to the left. There is extensive ventral spondylosis (arrowheads) between the tenth (10) and fourteenth (14) thoracic vertebrae in this 13-year-old international show jumper stallion.

Vertebral Bodies and Disks of the Thoracolumbar Region

Lesions of the vertebral bodies are less commonly found in horses²⁸ and cannot be imaged by ultrasonography in the thoracolumbar area (except caudal to L4 with a transrectal approach). These lesions include the following^{17,28,31,32}:

1. Ventral, ventrolateral, or lateral bony proliferation (often called vertebral spondylosis); these lesions are mainly found in the midthoracic area (Figure 52-21), but they can be seen in the lumbar area. Lesions range from small osseous spurs to complete bone bridges resulting in ankylosis. Although single lesions can occur, often several adjacent vertebrae are affected.²⁸
2. Vertebral body deformation (trapezoid shape) of the caudal thoracic vertebrae
3. Deformation of the adjacent vertebral head and fossa (disk enthesopathy) found in the caudal thoracic area

Fig. 52-22 • Lateral scintigraphic image of the thoracolumbar region of a 2-year-old Thoroughbred filly with back pain and loss of performance. There is a focal region of increased radiopharmaceutical uptake at the thoracolumbar junction (arrow), compatible with a laminar stress fracture.

4. Ski jump deformation (dorsal bony extension of the vertebral fossa) found in the caudal thoracic area
5. Fracture
6. Subluxation and intervertebral disk compression or protrusion

These lesions have been found in horses with a history or clinical manifestations of back pain—acute, intermittent, and chronic—and are considered to be of likely clinical significance. However, spondylosis also is an incidental finding in low-level performance horses with no history or clinical manifestations of back pain. Spondylosis was identified in 23 of 670 (3.3%) horses with back pain, usually occurring between T10 and T14.²⁶ There was a range of one to five lesions (mean 2.3). However, only nine of the 23 horses had spondylosis as the sole osseous lesion; the remainder also had impingement of the dorsal spinous processes and/or OA of the synovial intervertebral articulations. Nuclear scintigraphy may help to identify spondylosis and to elucidate the clinical significance of these findings in horses with back pain; however, not all lesions have IRU. In 17 of 23 horses with spondylosis that underwent scintigraphic evaluation, 64.7% had IRU associated with spondylosis, but only 33.3% of horses with lesions identified radiologically had IRU.²⁶ Extensive spondylosis may potentially limit back mobility, despite the absence of IRU.

Fracture and/or subluxation of a thoracolumbar vertebral body normally results in neurological abnormalities, but occasionally horses have acute severe back pain, with rapid atrophy of the epaxial musculature, but no evidence of ataxia.

Vertebral laminar stress fractures have been identified using nuclear scintigraphy in young TB flat race horses with loss of performance and clinical evidence of back pain (Figure 52-22). They have been seen most commonly at the thoracolumbar junction and in the lumbar vertebrae. In a post mortem sample of TB race horses, 18 (50%) of 36 specimens had evidence of vertebral stress fractures.³³

The Lumbosacral Joint

The lumbosacral joint (see also Chapter 50) and the intertransverse joints are evaluated ultrasonographically per rectum. Clinically significant abnormalities include²¹:

1. Congenital lumbosacral ankylosis, with reduced size or absence of the intervertebral disk
2. Focal loss of echogenicity of the intervertebral disk consistent with disk degeneration
3. Focal hyperechogenic regions in the intervertebral disk consistent with dystrophic mineralization
4. Ventral herniation of the intervertebral disk
5. Ventral subluxation of the sacrum
6. Osseous irregularities of the intertransverse articulation(s)

Muscle Injury

See Chapter 83 for a discussion of muscle injury.

PROGNOSIS

The prognosis for horses with any back lesion depends on a number of factors, including the individual pain tolerance of the horse, the skill of the rider and trainer, the discipline in which the horse is involved, and the type, number, and severity of lesions. Vertebral lesions are tolerated better by flat race horses than by Three Day Event horses, show jumpers, and dressage horses. Racing trotters tolerate vertebral lesions poorly. The prognosis for each lesion is not influenced by the level of work but more by the rider's or trainer's ability to exploit the horse despite its problems. A horse with an acute isolated supraspinous ligament injury has a good long-term prognosis, whereas horses with restricted mobility of the back caused by extensive kissing spines or type 6 or 7 synovial intervertebral articulation lesions have a poor prognosis. Horses with grades 3 and 4 dorsal kissing spines have a guarded prognosis, as do those with ventral kissing spine lesions. The prognosis for horses with synovial intervertebral articulation lesions depends on severity and the number of joints affected. Horse tolerance of ventral thoracic spondylosis seems to vary more, but generally the larger the number of vertebrae affected, the poorer the prognosis.

SPECIFIC MANAGEMENT

The general aims of management of back problems are to remove pain and to make the horse as comfortable as possible, as soon as possible, to allow it to be exercised to avoid further muscle loss and to promote muscle function and strength. Medical treatment aims to remove pain and muscle spasm.

Systemic Treatment

Treatment of horses with back pain with nonsteroidal anti-inflammatory drugs (NSAIDs) usually has disappointing results. Many horses are brought in for in-depth investigation of the cause of back pain because of lack of response to treatment with phenylbutazone or other NSAIDs. Treatment of muscle spasm with myorelaxants is indicated and sometimes useful; for example, thiocolchicoside (2 to

4 mg/100 kg twice weekly for 4 weeks) and methocarbamol (10 mg/kg intravenously). Repeated treatments may be necessary.

Intravenous infusion of tiludronate has resulted in improvement in clinical signs associated with OA of the synovial intervertebral articulations³⁷ and may also be indicated for treatment of osseous abnormalities associated with the lumbosacral joint.

Local Injections

Local perispinal or interspinal injections of corticosteroids, sometimes in association with myorelaxants or Sarapin (High Chemical Company, Levittown, Pennsylvania, United States), are used to treat horses with kissing spines: flumethasone (0.5 to 1 mg/injection site with a maximum total dose of 4 mg); dexamethasone (isonicotinate, 1.5 to 2.5 mg/injection site, with a maximum total dose of 10 mg); or methylprednisolone acetate (40 to 60 mg/injection site, with a maximum total dose of 200 mg).

Horses with OA of the synovial intervertebral articulations are treated by deep paramedian injections of corticosteroids (see the previous discussion) into the multifidus muscle on each side at the level of the lesion, 2 cm apart from the median plane, using 9- to 11-cm needles. These local injections are best performed using ultrasonographic guidance (Figure 52-23). Injections are made into the multifidus muscles that provide proprioceptive information on intervertebral movements. Therefore we suggest that the use of Sarapin is contraindicated in this situation. Local infiltrations can be performed alone or with mesotherapy.

Horses with lesions of the lumbosacral joint are treated by deep paramedian injection of corticosteroids with Sarapin or local anesthetic solution under ultrasound guidance.²¹ The needle is inserted 4 cm from the median plane on a line connecting the cranial aspects of the tubera coxae. The needle is directed obliquely caudally and is inserted under the ilial wing until contact is made with

bone in the vicinity of the axial aspect of the lumbosacral intertransverse joint. This is repeated on the left and right sides.

Mesotherapy

Mesotherapy is a technique that has been used for more than 40 years in France and consists of intradermal injections with short and thin needles (5 mm long) in the dermatomes corresponding to the site(s) of the lesion(s).

The principle is based on the theory of the gait control of pain, which takes place in the dorsal horn of the spinal cord. According to this theory, which is currently controversial, type I and II nerve fibers coming from the skin have collateral fibers that can inhibit the conduction of information in the spinothalamic fasciculus, transmitting painful information from deep structures of the same spinal segment to the thalamus and cerebrum.

After aseptic preparation of the skin, mesotherapeutic injections are usually made using a local anesthetic solution (lidocaine, 140 mg), a short-acting corticosteroid (dexamethasone, 15 mg), and a myorelaxant (thiocolchicoside, 20 mg). Injection with only saline solution may also have beneficial effects. Because most horses are sensitive to the procedure, the horse is placed in stocks, and the use of a twitch and sedation are recommended. A multiinjector (Coveto, Montaigu, France) is used. These intradermal injections are performed at the level of the lesion and caudal to it, taking into account the caudal orientation of the segmental nerves. For example, if one is treating kissing spines between T10 and T15, the treated region extends from T10 to L1. If the lesions involve the synovial intervertebral articulation between T17 and L2, the treated area should extend between T17 and the lumbosacral junction. If lesions are at the lumbosacral junction, the treated area should extend caudally to the croup. Two to three rows of injections are made on each side of the median plane.

After local injections or mesotherapy, the horse is restricted to light work on the lunge, without a surcingle, for 3 days. Normal training is progressively resumed over 5 days. A substantial improvement is anticipated within 7 to 14 days. If improvement is limited, mesotherapy should be repeated 2 to 3 weeks after the first treatment. The expected duration of action varies between 3 and more than 12 months. In horses with chronic pain, ideally a maximum of two local infiltrations should be performed each year with, or alternately with, mesotherapy.

Acupuncture

Acupuncture can be useful for treating chronic pain in some horses (see Chapter 92); however, relief of clinical signs may only be short term.³⁴

TRAINING MANAGEMENT

With the medical treatment to reduce pain, modification of the training program is an essential part of the management of back problems.³⁵ The aims of the exercise management are to avoid further muscle atrophy and to develop the back proprioceptive control and intervertebral stability. Rest is contraindicated, except in untreatable horses that are not improved by any kind of treatment and

management. The general recommendations include the following:

- Check the saddle fitting.
- In young horses, recognize that training must be progressive.
- Use a progressive warm-up program, first on the lunge without a saddle, then on the lunge with a saddle, then with the rider at walk, and so on. The use of a Pessoa or chambon when the horse is worked on the lunge may be of benefit.
- After the warm-up period at the walk, in sports horses, first work at the canter rather than at the trot. During cantering, the vertebral column undergoes only one slow and active flexion/extension cycle per stride, whereas the vertebral column undergoes two passive flexion/extension movements per stride at the trot.
- Identify and then remove every exercise that induces discomfort. For example, do no short turns to the right for 2 weeks, and then reassess if the horse is more comfortable turning to the right.

Some physical exercises, such as lowering of the neck (flexion of the cervicothoracic junction), may have a therapeutic value because they induce an associated thoracic flexion, which provides more support to the weight of the rider. A separation of the spinous processes reduces the contact between them.^{35,36} An elongation of the strong epaxial muscles reduces muscle contraction.³⁵

Exercises to increase hypaxial muscle strength may also be of clinically significant benefit.

ALTERNATIVE MEDICINES

Much interest exists in using alternative therapeutic techniques to manage back pain in horses. Once a clear diagnosis is established, alternative techniques, if appropriately applied and objectively assessed for each pathological entity, may be useful adjunctively in managing horses with back pain (see Chapters 93 through 96). Collaboration with a specialized physiotherapist or chiropractor may be of major benefit.

SURGERY

Surgical treatment of kissing spines by resection of the summit of one or more spinous processes has been successful in some horses that had not responded to conservative management.³⁹⁻⁴² Case selection is important and should be restricted to horses with lesions only involving the dorsal aspect of the spinous processes, without other clinically significant osseous abnormalities. A postoperative convalescent period of 6 months is generally required. Twenty-seven of 50 Warmblood horses (54%) used for dressage or show jumping returned to full athletic function at the previous level of performance.³⁹ One hundred fifty of 209 horses (72%) used for various disciplines returned to full work after removal of the summits of one to six dorsal spinous processes, although the level of work was not specified.⁴⁰ There was no significant difference between the number of spines removed and the outcome; however, in the authors' experience, the greater the number of spinous processes affected, the more guarded the prognosis for return to full athletic function as a sports horse.

Chapter 53

The Cervical Spine and Soft Tissues of the Neck

Sue J. Dyson

This chapter discusses disorders of the neck that may give rise to lameness or poor performance or result in an abnormal neck shape, abnormal neck posture at rest or while moving, or neck stiffness. Transient neurological conditions, conditions caused by trauma resulting in other injuries, and gait abnormalities that may be confused with lameness are considered, but those associated with compression of the cervical spinal cord are discussed in Chapter 60.

ANATOMY

The neck consists of seven cervical vertebrae, which articulate both by intercentral articulations and by synovial articulations, which have large joint capsules to accommodate the degree of movement between adjacent vertebrae. Interposed between the vertebral bodies are intervertebral fibrocartilages to which is attached the dorsal longitudinal ligament, which lies on the floor of the vertebral canal. The ligamentum flavum connects the arches of adjacent vertebrae. The atlas (the first cervical vertebra) and the axis (the second cervical vertebra) have a unique shape and specialized joints. The atlanto-occipital joint is a ginglymus joint, which permits flexion and extension and also a small amount of lateral oblique movement. The atlantoaxial joint is a trochoid or pivot joint; the atlas and head rotate on the axis. The ligament of the dens is strong and fan shaped and extends from the dorsal surface of the odontoid peg (dens) to the ventral arch of the axis. The ligamentum nuchae extends from the occiput to the withers and consists of funicular and lamellar parts. The lamellar part separates the two lateral muscle groups. The atlantal bursa is interposed between the funicular part of the ligamentum nuchae and the dorsal arch of the atlas; a second bursa may exist between the ligament and the spine of the axis. The muscles of the neck can be divided into lateral and ventral groups. The neck has eight cervical nerves, the first of which emerges through the intervertebral foramen of the atlas, the second through that of the axis, and the eighth between the seventh cervical vertebra and the first thoracic vertebra. The sixth to eighth cervical nerves contribute to the brachial plexus.

REASONS FOR CLINICAL PRESENTATION

A horse may be presented for evaluation of the neck for a variety of reasons. The horse may have a history of a fall on the neck while jumping, having reared up and fallen over backward, or having collided with another horse or

solid object, thus sustaining neck trauma. The horse may have neck pain from having pulled backward while being tied up. The horse may have no history of trauma but have abnormal neck posture, swelling, a stiff neck, neck pain, or difficulties in lowering and raising the head. The horse may have a performance-related problem such as unwillingness to work on the bit, an unsteady head carriage, or abnormal head posture. A neck lesion should also be considered in a horse with forelimb lameness when pain cannot be localized to the limb. Subtle hindlimb gait abnormalities, such as a tendency to stumble, may be caused by a neurological deficit without overt ataxia, reflecting a compressive lesion of the cervical spinal cord.

CLINICAL EXAMINATION

It is important to recognize that head and neck carriage depends in part on conformation: the way in which the neck comes out of the shoulder and the shape of the neck. The shape of the neck is also influenced by the way in which the horse works. If a horse carries the head and neck high, with the head somewhat extended, the ventral strap muscles tend to be abnormally well developed, resulting in a ewe-neck conformation. Many horses naturally bend more easily to the right than to the left or vice versa, and the muscles on the side of the neck, especially dorsocranially, are developed asymmetrically. Such asymmetry is particularly obvious if the neck is viewed from above by the rider. If a horse is excessively thin, then the cervical vertebrae become prominent and the caudodorsal neck region becomes dorsally concave, whereas in a fit, well-muscled horse that works regularly on the bit, this region is dorsally convex. Most stallions and many native pony breeds have a prominent dorsal convexity to the neck region, resulting in a cresty appearance. A horse that is excessively fat tends to lay down plaques of fat throughout the body, including the neck region, and this can be misinterpreted as abnormal neck swelling.

If a horse is particularly thick through the jaw, that is, has a large mandible, it is physically difficult to work on the bit (i.e., flexing at the poll so that the front of the head is in approximately the vertical position). Although neck pain can cause a reluctance to work on the bit, more common causes include rider-associated or training problems, mouth pain, forelimb or hindlimb lameness, and back pain. Some horses strongly resist the rider's aids to work on the bit, despite the absence of pain. The use of artificial aids such as draw or running reins, which give the rider a mechanical advantage, may help to break a vicious cycle and encourage the horse to become more submissive and compliant. Similarly, work on the lunge line using a chambon (a device that runs from the girth via a headpiece to the bit rings) can encourage the horse to work in a correct outline and develop fitness and strength of the appropriate musculature. Working the horse in trot over appropriately spaced trotting poles can also help to encourage a horse to work in a correct outline, with a round and supple back.

A rider may complain of neck stiffness or difficulties in getting a horse to bend correctly in a circle. Although this may be caused by neck pain, neck stiffness may be a

protective mechanism by the horse to avoid pain associated with lameness, especially forelimb lameness. A horse with left forelimb lameness, for example, may be reluctant to bend properly to the left, and when unrestrained by a rider on the lunge, on the left rein may hold the neck and head slightly to the right, giving the appearance of looking out of the circle. Thus load distribution is altered and lameness minimized. Such lameness actually may not be evident during riding, although this may be the only circumstance under which the rider recognizes the problem. The lameness may be more obvious on the lunge or even in hand in straight lines. When a horse has an abnormal neck and/or head posture, a comprehensive clinical evaluation of the entire horse should be performed. Neck pain or abnormal posture may reflect a primary lesion elsewhere (e.g., central or peripheral vestibular disease, fracture of the spinous processes of the cranial thoracic vertebrae, a mediastinal or thoracic abscess, or a systemic disease such as tetanus).

Detailed examination of the neck should include assessment of the neck conformation, the shape and posture at rest, and the position of the head relative to the neck and trunk. The veterinarian should note any patchy sweating or change in hair color reflecting intermittent sweating that may suggest local nerve damage. Look carefully at the musculature to identify any localized atrophy. Palpate the right and left sides of the neck to assess symmetry and the presence of abnormal swellings or depressions and to identify any neck muscle pain, tension, or fasciculation. Deep palpation should be performed on the left and right sides of the neck to identify pain.

A series of nine equidistant acupoints (acupuncture points) exist along an arc on the crest of the neck.¹ The most cranial is in the depression just cranial to the wing of the atlas and just caudal to the ear. The most caudal point is a few centimeters dorsocranial to the dorsocranial

aspect of the scapula. Six intervertebral acupoints also exist between the vertebrae. An abnormal response to firm palpation of these points may reflect neck pain.

Neck flexibility should be assessed from side to side and up and down. This can be done by manually manipulating the neck, but many normal horses resist this. Holding a bowl of food by the horse's shoulder to assess lateral flexibility is helpful. Ideally the horse should be positioned against a wall, so that the horse cannot swing its hindquarters away from the examiner during this assessment. The clinician should try to differentiate between the horse properly flexing the neck and twisting the head on the neck. Compare flexibility to the left and to the right. To assess extension of the neck, the veterinarian should evaluate the ease with which the horse can stretch to eat from above head height. Observing the horse grazing is helpful to assess ventral mobility of the neck. Especially with lesions in the caudal neck region a horse may have to straddle the forelimbs excessively to lower the head to the ground to graze (Figure 53-1, A). The horse should also be observed moving in small circles to the left and the right, and loose on the lunge.

Assessing skin sensation and local reflexes, such as the cervicofacial and the thoracolaryngeal reflexes, and comparing carefully the right and left sides may be useful. The consistency and patency of the jugular veins should be evaluated.

The horse should be observed moving in hand and on the lunge, and if necessary should be ridden, to assess neck posture and the presence of neurological gait abnormalities, restriction in forelimb gait, or lameness. The clinician should note how any gait abnormality is influenced by the positions of the head and neck. Forelimb lameness occasionally is associated with a primary cervical lesion, usually, but not invariably, together with other clinical signs referable to the neck.²

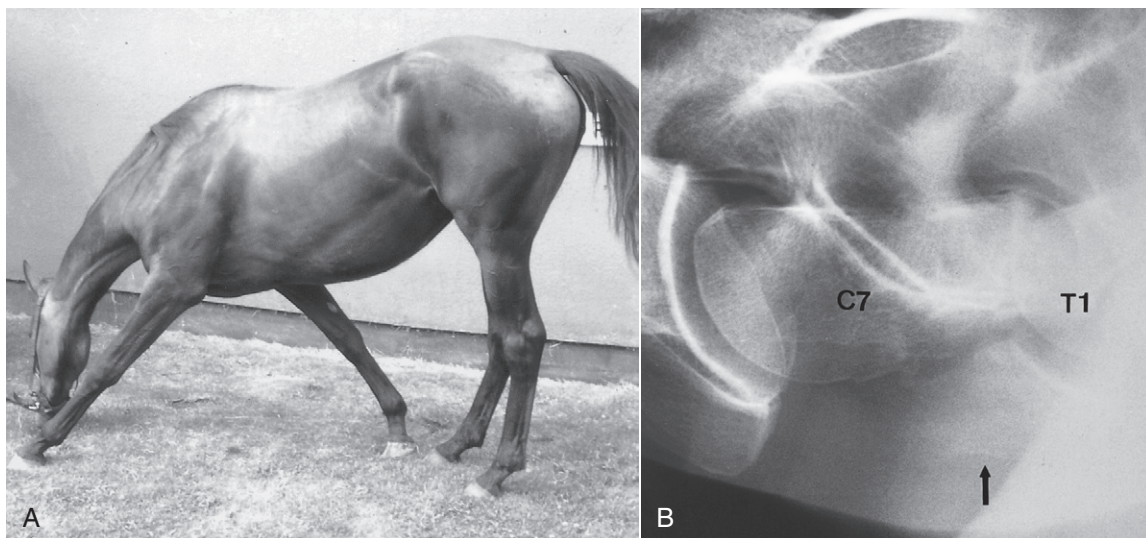

Fig. 53-1 • A, A 3-year-old Thoroughbred filly with severe neck pain and restricted forelimb gait associated with a displaced articular fracture of the ventral processes of the seventh cervical vertebra. The horse must adopt the straddled forelimb stance to lower the head to graze. **B**, Lateral radiographic image of the caudal cervical vertebrae (sixth cervical to first thoracic vertebrae) of the same horse. Cranial is to the left. The ventral processes of the seventh cervical vertebra are displaced (arrow). The intercentral joint space between the seventh cervical (C7) and first thoracic (T1) vertebrae is narrowed greatly, with abnormal orientation of the vertebral bodies.

IMAGING CONSIDERATIONS

Radiography and Radiology

Comprehensive radiographic examination of the neck requires at least five exposures, assuming that large cassettes or imaging plates are used, including the poll, cranial, midneck and caudal neck regions and the base of the neck to evaluate the first and second thoracic vertebrae.³ Lateral-lateral images are obtained easily in the standing position, but ventrodorsal images are best obtained with the horse in dorsal recumbency under general anesthesia, except in small ponies and foals. Positioning of the neck is important, because any rotation of the head and neck makes evaluation difficult, in particular the synovial articulations. Relatively large exposures are required for the more caudal neck regions, so radiation safety is important, and the cassette should be supported in a holder, not held by hand. A grid is useful, especially in the caudal neck region, to reduce scattered radiation. Obtaining exposures from left to right and right to left may be useful. Lateral oblique images of the cervical vertebrae may give additional information.

A number of variations of the normal radiological appearance of the cervical vertebrae should not be mistaken for lesions. A spur on the dorsocaudal aspect of the second cervical vertebra may project into the vertebral canal. The ventral processes of the sixth cervical vertebra and occasionally other vertebrae have small separate centers of ossification. The ventral lamina on the sixth cervical vertebra may be transposed onto the ventral aspect of the seventh cervical vertebra, unilaterally or bilaterally. The seventh cervical vertebra has a small spinous process, which may be superimposed over the synovial articulation between the sixth and seventh cervical vertebrae and should not be confused with periarticular new bone. In older horses small spondylitic spurs may be seen on the ventral aspect of the vertebral bodies. Modeling of the dorsal synovial articulations between the fifth and sixth and between the sixth and seventh cervical vertebrae is common in middle-aged and older horses³⁻⁵ (Figure 53-2).

Major radiological abnormalities such as fusion of two adjacent vertebrae can be present subclinically, in part because of the great mobility between adjacent vertebrae (Figure 53-3, A). The clinical significance of such lesions may also be determined by the athletic demands placed on the horse.

Nuclear Scintigraphy

Lateral and ventral scintigraphic images of the neck can be obtained. Ideally, images should be obtained from the left and right sides. In normal horses there is usually greater radiopharmaceutical uptake in the synovial articulations between the fifth and sixth and sixth and seventh cervical vertebrae, compared with the more cranial articulations reflecting the mobility of these joints and the biomechanical forces imposed on these articulations. There is often greater radiopharmaceutical uptake in the odontoid peg (dens) of the axis, compared with the surrounding vertebrae.

Increased radiopharmaceutical uptake (IRU) is not necessarily synonymous with a lesion that is clinically significant; therefore images must be interpreted with care (see Figure 53-3, B). The clinician should compare images obtained from the left and right sides carefully, because

Fig. 53-2 • A, Lateral radiographic image of the caudal cervical vertebrae of normal 4-year-old Thoroughbred. The synovial articulations between the fifth (C5) and sixth (C6) cervical and sixth and seventh (C7) cervical vertebrae are outlined smoothly. The intervertebral foramina are distinct. Compare with part **B** and Figure 53-8. **B**, Lateral radiographic image of the caudal cervical vertebrae of 9-year-old clinically normal horse. The synovial articulations are enlarged between the fifth (C5) and sixth (C6) cervical vertebrae and particularly between the sixth and seventh (C7) cervical vertebrae.

disparity in radiopharmaceutical uptake may be clinically significant. The veterinarian should evaluate the actual conformation of the synovial articulations, because a change in shape even without IRU may be important. Fractures are not always associated with prominent IRU, and lesions may be missed in the caudal neck region because of the overlying muscle mass and the scapulae.

Ultrasonography

The indications for ultrasonographic examination include evaluating swellings, assessing painful muscles and lesions of the ligamentum nuchae, assessment of the intercentral and synovial vertebral articulations (facet joints), documenting jugular vein thrombophlebitis, and administering ultrasound-guided injections.⁶⁻⁸

Computed Tomography

Computed tomography (CT) has the potential to give three-dimensional information about the cervical vertebrae and with contrast-enhanced studies can give information about spinal cord and nerve compression. However, general anesthesia is required, and it is practical to image only the cranial cervical vertebrae.⁹⁻¹¹

Fig. 53-3 • A, Lateral radiographic image of a 15-year-old Arabian international-level endurance horse that had been competing successfully with no clinical signs referable to the neck. There is abnormal angulation between the third (C3) and fourth (C4) cervical vertebrae. The vertebral bodies of the third and fourth cervical vertebrae are osteoporotic. Extensive new bone has formed over the ventral aspect of the intercentral articulation between the third and fourth cervical vertebrae, with narrowing of the intercentral joint space and thinning of the caudal end plate of the third cervical vertebra. The ventral profile of the more cranial aspect of the third cervical vertebra is abnormal. **B,** Lateral scintigraphic image of the midneck region of the same horse. Note the increased radiopharmaceutical uptake in the vertebral body of the fourth cervical vertebra (arrowhead).

Thermography

Thermographic examination of the neck is discussed in detail elsewhere (see Chapters 25 and 95). However, I have found thermography of limited usefulness, except for identifying acute superficial muscle injuries.

Electromyography

Electromyography (EMG) can be used to quantify the motor unit action potential and to identify insertional activity and pathological spontaneous electrical activity in muscle that can help to differentiate between myopathy and neuropathy and to localize the source of a lesion. It has been suggested that EMG can be used to help to determine the clinical significance of radiological abnormalities of the cervical vertebrae by detection of evidence of neuropathy.¹²

OTHER DIAGNOSTIC TESTS

In selected horses with neck pain, valuable information may be obtained from hematological and serum biochemical

tests. Measuring *Brucella* titers and tuberculosis testing are occasionally useful. Bone biopsy may be valuable for determining the cause of some bony lesions.

CLINICAL CONDITIONS

Occipito-Atlantoaxial Malformation

Occipito-atlantoaxial malformation (OAAM) is a congenital abnormality,¹³ and although it can occur in any breed,¹⁴ OAAM appears to be a heritable condition in Arabian horses¹⁵ (see Chapter 123). Clinical signs are usually recognizable within the first few weeks of life and include an abnormal neck shape in the poll region, with prominence on the left or right sides or both, and/or scoliosis (Figure 53-4, A). These signs are best appreciated when viewed from above. Usually no associated soft tissue swelling or pain exists, although an abnormal clicking sound may be audible because of subluxation of the atlantoaxial joint. The horse may have an abnormal limitation of movement in the poll region. The gait should be assessed carefully for neurological abnormalities; however, in many horses no neurological gait deficits are apparent.

Diagnosis is confirmed radiologically using lateral and ventrodorsal views. Bony abnormalities include fusion of the atlas to the occiput, atlantoaxial luxation, and abnormal shapes of the atlas and axis, often asymmetrical (see Figure 53-4, B).

No treatment is available for horses with OAAM. Prognosis for athletic function is determined by the degree of neck stiffness. Because of the heritable nature of this condition in Arabian horses, breeding of affected horses or the sire or the dam is inadvisable.

Other Congenital Abnormalities

OAAM is the most common congenital abnormality of the cervical vertebrae, but congenital torticollis is seen occasionally, caused by malformation of more caudal cervical vertebrae. Vertebral body fusion usually is seen with a meningocele, resulting in neurological abnormalities, and therefore is not considered further.

Subluxation of the First and Second Cervical Vertebrae

Subluxation of the first and second cervical vertebrae is an unusual condition, probably related to trauma such as a fall, although the horse may have no recent history of such.¹⁶⁻²² The condition is associated with damage of the ligament of the dens or the ventral longitudinal ligament between the first and second cervical vertebrae or occurs secondary to a fracture of the dens.^{17,18} An affected horse usually has a stiff neck and a tendency for the head and neck to be somewhat extended (Figure 53-5, A). Differentiating between neck pain and stiffness may be difficult. An audible clicking noise may emanate from the region, and occasionally abnormal movement between the vertebrae can be appreciated. Because of the relatively wide sagittal diameter of the vertebral canal at this site, generally no associated compression of the cervical spinal cord occurs. Occasionally, neurological abnormalities are seen in horses with a displaced fracture of the dens.²²

Diagnosis is based on radiographic examination, using lateral-lateral images with the neck in natural (neutral) and

Fig. 53-4 • A, Dorsal view of the poll region of a 6-month-old Thoroughbred filly with an abnormal asymmetrical shape and scoliosis of the cranial neck region and neck stiffness associated with occipito-atlantoaxial malformation. **B,** Ventrodorsal radiographic image of the same horse. Note the distorted shape of the atlas, its fusion with the occiput, and the abnormal orientation of the intercentral articulation between the first (C1) and second (C2) cervical vertebrae.

extended positions. Radiological abnormalities may include abnormal orientation between the first and second cervical vertebrae (see [Figure 53-5, B](#)). The position of the dens may be abnormal, resulting in narrowing of the space between it and the dorsal lamina of the vertebral arch of the first cervical vertebra. In a study of yearling Thoroughbreds the mean minimum sagittal diameter was 34 mm and the minimum was 26 mm.²⁰ Narrowing of the distance between the vertebral arch of the first and second cervical vertebrae may occur in the extended versus neutral position of the neck. The shape of the dens may be altered because of secondary new bone formation. Occasionally the dens is fractured, usually at the junction between the odontoid process and the body of the vertebra.²² The synovial facet joints between the first and second cervical vertebrae may be altered in shape.

Foals with fractures of the odontoid peg have been successfully treated by surgical stabilization, but limited information exists about long-term prognosis.^{18,19,21} Foals with subluxation without neurological abnormalities have a good prognosis for life; prognosis for athletic function is fair, depending on the intended level of competition. No reports of successful management of subluxation in adult horses exist, and the prognosis for return to athletic function with conservative management is poor. However, it was reported that four of five horses with an acute fracture of the dens returned to athletic function, despite neurological gait abnormalities at the time of acute injury, although one had a tendency to trip.²²

Subluxation of the Sixth and Seventh Cervical Vertebrae

Subluxation of the sixth and seventh cervical vertebrae is usually recognized in adult horses with a complaint of lack

of hindlimb power or with difficulties in performing movements requiring collection or, if a breeding stallion, difficulties in mounting either mares or a dummy. Careful clinical examination usually reveals mild-to-moderate hindlimb ataxia. Radiographic examination reveals dorsal displacement of the head of the seventh cervical vertebra. Subluxation of the sixth and seventh cervical vertebrae has less commonly been identified as a cause of bilateral forelimb lameness.²³

Insertional Desmopathy of the Nuchal Ligament and Injury to Semispinalis

The nuchal ligament is a bilobed structure, fans at its insertion on the occiput, and is surrounded by muscle, the semispinalis to the left and right and the rectus capitis ventrally. New bone formation at the insertion on the occiput may be an incidental finding. Examination of 302 Warmbloods from 1 to 22 years of age revealed new bone in 85%. A postmortem study of Warmbloods revealed a similar high proportion of horses with chondroid metaplasia at the insertion of the ligament and dystrophic mineralization.²⁴ A smaller radiological study of Thoroughbreds revealed new bone on the caudal aspect of the occiput in only 5%.²⁴

Horses with insertional desmopathy of the nuchal ligament or injury to the tendon of insertion of semispinalis often have a history of trauma to the region (e.g., pulling back when tied up) or an excessive amount of lunging exercise while restricted with side or draw reins.²⁴⁻²⁶ Horses should be examined while being lunged, with and without side reins, and ridden. Clinical signs include permanent resistance against the reins, with difficulty or unwillingness to lower and flex the head and neck when ridden and poor flexion at the poll. In contrast to horses with back pain,

Fig. 53-5 • A, A 9-year-old advanced event horse that had shown neck stiffness since traveling from the United States to Great Britain. The head is extended somewhat, and there was significant neck stiffness or guarding. A clicking sound emanated from the cranial neck region. **B,** Lateral-lateral radiographic image of the cranial neck region of the same horse. There is an abnormal orientation between the first (C1) and second (C2) cervical vertebrae. Space between the dorsal aspect of the dens and the ventral aspect of the dorsal lamina of the vertebral arch of the first cervical vertebra is reduced. The dorsal aspect of the dens is irregular because of new bone formation. Postmortem examination confirmed partial disruption of the ligament of the dens.

hindlimb impulsion is usually good. The horse may have a tendency to rear or shake its head.

Pain cannot usually be elicited by palpation. Radiological examination may reveal new bone on the caudal aspect of the occiput that may extend farther ventrally and dorsally than the actual insertion of the ligamentum nuchae (Figure 53-6). Mineralization sometimes is seen dorsal to the first cervical vertebra as an incidental radiological finding, unassociated with clinical signs. Scintigraphic examination findings may be negative. Ultrasonographic examination is not easy, and interpretation is difficult. Mineralization within the ligament may cause shadowing artifacts. CT offers the most sensitive means of detecting lesions in either the nuchal ligaments or the border of

Fig. 53-6 • Lateral-lateral radiographic image of the head of an 8-year-old Warmblood show jumper with a history of reluctance to accept and go forward to the bit and stiffness. There is enthesophyte formation on the caudal aspect of the occiput at the insertion of the nuchal ligament (arrows). The horse responded well to local infiltration with corticosteroids and local anesthetic solution and modification of the training program.

insertion of semispinalis.²⁴ Diagnosis depends on a positive response to infiltration of local anesthetic solution. Fifteen milliliters of mepivacaine are infiltrated on the left and right sides, and the response is assessed after 15 to 30 minutes. Care must be taken not to inject into the epidural space, which will result in ataxia.

Treatment consists of repeated infiltration of corticosteroids, Traumeel (a homeopathic remedy), and local anesthetic solution and modification of the training program, with no work on the bit for 8 weeks.²⁶ The horse should be worked principally in straight lines. In the stable the horse should be encouraged to flex the poll region gently from side to side and up and down. The use of acupuncture or magnetic field therapy, laser therapy, ultrasound, or shock wave therapy may help some horses. The results vary. Seventy percent of 26 horses return to full work, although not all are completely normal. Extracorporeal shock wave therapy, two or three applications at 14-day intervals, in addition to 4 weeks of work without requiring flexion of the poll has been reported to be successful in resolving clinical signs in 12 of 22 horses and in improving signs in six other horses.²⁷ Surgical treatment by transection of the nuchal ligament and the fascia of semispinalis has resulted in improvement in a small number of horses refractory to conservative management.²⁴

Disorders of the Neck Musculature

The clinical significance of localized muscle soreness and/or tenseness is poorly understood and documented. I have had experience with a number of horses with subtle performance problems, including slight neck stiffness, reluctance to work properly on the bit and to accept an even contact, and intermittent, slight gait irregularities associated with soreness around and in front of the wings of the axis. Clinical improvement has been seen after relief of this pain by rapid and sudden rotation of the head about the axis.²⁴

Many horses resent firm palpation of the brachiocephalicus muscles at the base of the neck. This may be more obvious in horses with forelimb lameness, especially those

with pain in the distal part of the limb. This muscle soreness is generally a secondary rather than a primary cause of lameness. Transient improvement in gait may be seen after local therapy using laser therapy, H-wave therapy, ultrasound, and/or massage.

Primary brachiocephalicus pain at the base of the neck has been seen in performance horses, causing subtle gait abnormalities at the walk when ridden, characterized by abnormal lifting of the neck as the limb was advanced and a shortened cranial phase of the stride ipsilateral to the sore muscle. Bilateral brachiocephalicus muscle pain has also been seen in association with throwing up of the head when in the air over a fence and on landing. Treatment of the sore muscles abolished this behavior.

Local muscle soreness also may be seen with a poorly fitting saddle or girth or with a rider who is unable to ride truly in balance with the horse. The primary problem must be addressed if treatment is to be successful. Some driving horses develop forelimb lameness that is seen only when the horse is pulling and may be associated with pressure from the harness. Adaptation of the harness may relieve the problem.

Some horses seem to need to learn how to use the neck and forelimb musculature to maximum advantage and have a restricted forelimb gait without appearing overtly lame. The gait is not altered by distal limb nerve blocks. Some improvement may be achieved by daily massage of the muscles at the base of the neck and manual full protraction of the forelimbs. This is combined with exercise to encourage the horse to lengthen the forelimb stride and to round the back. Lunging in a chambon, trotting over appropriately placed trot poles, and repeatedly lengthening and shortening the stride all may be beneficial. Trotting down the tramlines in a field of corn or rapeseed can also be of enormous help.

Occasionally as the result of a fall or pulling back when tied, acute severe neck muscle soreness develops. The horse is best treated initially with nonsteroidal antiinflammatory drugs (NSAIDs), rest, and local physiotherapy, followed by progressive remobilization when the acute muscle soreness has subsided. The prognosis is good.

I have examined several horses that have had episodic transient attacks of profound neck pain and stiffness, holding the neck relatively low. In some horses a severe unilateral forelimb lameness occurs, often resulting in the limb being held in a semiflexed position at rest. These attacks vary in duration (hours to days), and generally horses have been completely normal between episodes. To date, neither a definitive cause nor an effective treatment has been identified for this syndrome. However, there is usually a very marked enlargement of the caudal cervical facet joints, with narrowing of the intervertebral foramen, and it is suspected that nerve root impingement may cause episodic pain. Careful manipulation of the caudal neck region may result in instantaneous relief of clinical signs.

Dystrophic mineralization is seen sometimes as an incidental radiological finding in the neck musculature, secondary to previous intramuscular injections.

Muscle Abscess

Horses sometimes develop localized muscle soreness and swelling at the site of intramuscular injection, especially

equine influenza injections, which can result in neck stiffness and a restricted forelimb gait. Signs usually resolve within 24 to 48 hours. Treatment is generally unnecessary, although hot packing and analgesia may be beneficial. More irritant drugs, such as iron injections, may result in the development of a sterile abscess.

The development of a single or multiloculated abscess cavity filled with malodorous material is usually a sequela to an intramuscular injection of a variety of drugs administered within the previous few weeks. Clinical signs include neck pain and stiffness, localized neck swelling with or without focal patchy sweating, and sometimes pyrexia. Diagnosis is based on the history and clinical signs and can be confirmed by ultrasonography. The abscess cavity is usually filled with anechogenic material surrounded by a hyperechogenic abscess wall.

Treatment is by surgical drainage, which is easily performed in the standing horse. The abscess cavity should be thoroughly lavaged. Systemic antimicrobial drugs usually are not required, unless clostridial myositis is suspected based on the fulminant nature of the condition (see Chapter 83). The prognosis for most horses with muscle abscesses is good, provided that adequate drainage is established. However, surgical removal of the entire abscess occasionally is required.

Osteoarthritis

Anatomical studies have shown that approximately 50% of normal mature horses have some unilateral or bilateral modeling of the synovial facet joints between the sixth and seventh cervical vertebrae. The modeling often is accompanied by extension of fibrocartilage across the cranial border of the dorsal arch of the seventh cervical vertebra and irregular enlargement of the articular processes.^{4,5} The spinous process of the seventh cervical vertebra may become flattened or fragmented by contact with the sixth cervical vertebra when the neck is extended. Radiologically these changes result in irregularity of the normally smooth outline of the synovial articulations. Similar modeling changes also occur in the synovial articulation between the sixth and seventh cervical vertebrae.²⁴ A bony knob may develop on the ventral aspect of one or both cranial articular processes at the articulations between the fifth and sixth cervical vertebrae and between the sixth and seventh cervical vertebrae. When well developed, this knob forms a buttress that impinges onto the body or the arch of the more cranial vertebra and forms a false joint. The buttress partially obliterates the intervertebral foramen, but it is often of no clinical significance.³⁻⁵ Buttresses occur at the articulation between the sixth and seventh cervical vertebrae in 18% of normal horses.⁴

The potential exists for large amounts of new bone associated with osteoarthritis of the cervical synovial articulations to encroach axially into the vertebral canal, resulting in compression of the spinal cord and hindlimb weakness and ataxia, or into the intervertebral foramen, resulting in nerve root compression with local or referred pain and possibly lameness and patchy sweating. Severe osteoarthritic change may progress to partial or complete fusion and thus neck stiffness. With enlargement of a synovial articulation also generally comes enlargement of the joint capsule, and synovial outpouchings or cysts may develop that may impinge on the spinal cord.

Fig. 53-7 • Slightly oblique lateral-lateral radiographic image of the caudal cervical region of a 7-year-old riding horse with mild right forelimb lameness and an abnormally low head and neck carriage. Lameness was unaltered by comprehensive diagnostic analgesia of the right forelimb. There is extensive modeling of the articular facet joints between the sixth (C6) and seventh (C7) cervical vertebrae, with a large radiodense mass with heterogeneous opacity extending dorsally. Obtaining a true lateral-lateral image was not possible. The obliquity of the radiograph makes it difficult to assess the intervertebral foramen. Postmortem examination revealed compression of the seventh cervical spinal nerve at the level of the foramen.

Radiological abnormalities associated with osteoarthritis include enlargement of one or more of the articular facets and alteration in joint space width (Figure 53-7). Widening of the joint space is usually associated with asymmetrical facet enlargement; narrowing is caused by articular cartilage degeneration. Pitted lucent zones may develop in the articular facets, with extension of the dorsal laminae between adjacent vertebrae and partial or complete obliteration of the adjacent intervertebral foramina. Sometimes fractures are seen dorsal to a joint. Abnormalities often develop on the left and right sides but are frequently asymmetrical. With substantial asymmetry of the synovial articulations the affected and immediately more cranial vertebrae may appear rotated on a lateral radiographic image, although the horse had appeared to be standing with its head and neck straight in the sagittal plane. Radiographic examination from left to right and from right to left and oblique radiographic images can help to determine on which side a unilateral lesion is present. A lesion that is close to the cassette is clearer and magnification is less than if the lesion is on the opposite side of the neck. Ultrasonography can also be used to demonstrate periarticular modeling and increased synovial fluid within a joint.

The clinical importance of osteoarthritis of one or more synovial articulations can be difficult to determine by clinical and radiographic examinations alone, except by exclusion. The greater the degree of abnormality and the larger the number of articulations involved, the more likely the condition is clinically significant. In normal horses, finding osteoarthritic change cranial to the articulation between the fifth and sixth cervical vertebrae is rare. Unilateral forelimb lameness has been seen with lesions between the fourth cervical and first thoracic vertebrae.² Nuclear

scintigraphic examination may give further information in horses with neck stiffness or forelimb lameness apparently not referable to the limb itself. Ultrasound-guided intraarticular analgesia may help to determine the clinical significance of radiological abnormalities (Figure 60-5).

In one report, seven of eight horses with forelimb lameness associated with radiological abnormalities of the cervical vertebrae also had subtle to obvious signs of neck pain.² Patterns of muscle atrophy in the neck and shoulder regions varied. The character of lameness varied. Radiological abnormalities included substantial modeling of the synovial articulations in the caudal neck region in three horses; a fourth had modeling and a fracture involving the synovial articulation between the fourth and fifth cervical vertebrae. One horse had abnormalities of the intercentral articulation between the seventh cervical and first thoracic vertebrae and a discrete mineralized fragment dorsal to it. Large lucent zones were identified in a vertebral body (the fourth and sixth cervical vertebrae) in two horses. A fracture of the vertebral body of the seventh cervical vertebra was seen in one horse.

Nerve root impingement in the caudal neck region may cause radicular or referred pain and account for forelimb lameness. Neck pain itself can also cause forelimb lameness. Compression of the seventh cervical nerve was confirmed post mortem in a horse with osteoarthritis of the articulations between the sixth and seventh cervical vertebrae and between the seventh cervical and first thoracic vertebrae.² Nerve root compression with severe osteoarthritis has also been demonstrated using contrast-enhanced CT.⁹

In horses with mild ataxia, neck stiffness or forelimb lameness associated with osteoarthritis of cervical synovial articulations, the response to rest and treatment with NSAIDs has been limited. Local periarticular or intraarticular infiltration of corticosteroids, performed using ultrasonographic guidance, may bring temporary relief. There is limited documented evidence for the efficacy and duration of effect of medication of the synovial articulations of the caudal cervical vertebrae. In a recent study of 59 sports or pleasure horses with ataxia, neck stiffness or pain, or obscure forelimb lameness, 19 horses (32%) returned to full function and 18 horses (31%) improved more than 50%.²⁸ However, the effect was generally short lived, with 55% showing improvement for a duration of less than 1 month to up to 6 months. The inclusion criteria for the study were poorly defined and follow-up results were based on the owners' subjective opinions. Epidural injection of corticosteroids performed with the horse under general anesthesia has been shown to result in relief of neck stiffness in a horse with osteoarthritis of the synovial articulation between the fourth and fifth cervical vertebrae and clinical evidence of nerve root compression.²⁹

Osteoarthritis, especially in the caudal neck region, may result in associated enlargement of the joint capsule(s) and subsequent pressure on the spinal cord. In horses with mild osteoarthritis obvious ataxia may not be seen, but the history may include the tendency to stumble or to knuckle behind, or lack of hindlimb impulsion. Such signs often have been attributed to lameness but are invariably unaltered by diagnostic treatment with NSAIDs. Clinical signs may be subtle and intermittent. Such horses usually show abnormal weakness if pulled to one side by traction on the tail while the horse is walking—the sway test. A normal

Fig. 53-8 • Lateral radiographic image of the caudal cervical vertebrae of 4-year-old dressage horse with mild hindlimb weakness and a tendency to stumble behind, especially in downward transitions from trot to walk. The synovial articulations between the fifth (C5) and sixth (C6) cervical and sixth and seventh (C7) cervical vertebrae are enlarged greatly (compare with Figure 53-2, A). The joint spaces are widened, reflecting asymmetrical modeling of the articular processes. There is a ventral buttress at the articulation of the sixth and seventh cervical vertebrae, with reduction in size of the intervertebral foramen.

horse easily may be pulled off line once, but then strongly resists. A weak horse can be pulled off line repeatedly. Weakness may also be apparent as the horse decelerates from trot to walk, with exaggerated up-and-down movement of the hindquarters and asymmetric hindlimb placement. This may result in irregular movement of each patella and may be confused with mild intermittent upward fixation or delayed release of the patella (see Chapters 46 and 48). At faster speeds the horse may look completely normal, although some affected horses demonstrate a remarkably croup-high canter when on the lunge. In a young horse, advanced osteoarthritis of one or more caudal cervical synovial articulations is strong circumstantial evidence of cause and effect (Figure 53-8). Definitive diagnosis in an older horse is much more difficult, because radiological evidence of osteoarthritis may be present without associated clinical signs. Myelography may help.³⁰ The prognosis is poor, and the horse may be potentially unsafe to ride. Surgical treatment can be considered and generally results in clinical improvement, but few sports horses become upper level athletes, and some develop recurrent ataxia several years later.

Diskospondylitis

A survey of the cervical intervertebral disks of 103 horses from birth to 23 years of age confirmed that they consisted solely of fibrocartilage, with no nucleus pulposus.³¹ Age-related degenerative changes were identified, but even with severe disintegration of the disks, no referable clinical signs had been apparent.

Diskospondylitis is a rare cause of neck pain, forelimb lameness, or ataxia.^{30,31} Although diskospondylitis is usually an infectious condition in dogs, no proven relationship occurs in the horse, and trauma may be an inciting cause. Lesions in the horse have been identified in the caudal neck region (the articulations between the sixth and seventh cervical vertebrae and the seventh cervical and first thoracic vertebrae) and between the third and fourth

cervical vertebrae in association with severe neck pain and a bilaterally short, stiff forelimb lameness or episodic, unilateral forelimb lameness. Occasionally a horse may be reluctant to work “on the bit.” High-quality radiographs are required for accurate diagnosis. Lesions are characterized by loss of the normal opacity of the cranial and caudal endplates of the affected vertebrae, with or without alteration in the intercentral joint space. Scintigraphic examination may help to localize the affected joint(s). Ultrasonography may be more sensitive in the identification of early bone lesions and abscess formation. The prognosis is guarded, although in one report a broodmare that was admitted with profound neck pain and periodic severe left forelimb lameness, associated with roughening of the endplates at the intercentral articulation between the sixth and seventh cervical vertebrae and narrowing of the intercentral space, after a collision with a fence, made a spontaneous recovery.³² A second horse was treated by surgical debridement of the disc space and implantation of a cancellous bone graft, with resolution of clinical signs.³³

Fracture

Fractures of the cervical vertebrae usually result from trauma: the horse rearing up and falling over backward or sideways; pulling back when tied up; or falling while jumping, usually at speed. Clinical signs are sudden in onset and include holding the neck in an abnormally low position, stiffness, a focal or more diffuse area of pain, with or without localized or more diffuse soft tissue swelling, and muscle guarding. Audible or palpable crepitus is sometimes detected. The horse may be unable to lower its head to the ground or may be able to do so only by straddling of the forelimbs (see Figure 53-1, A). Associated hindlimb and forelimb ataxia may be apparent, which can be transient and self-resolving, or persistent. Patchy sweating and localized muscle atrophy may develop. Occasionally an associated unilateral or bilateral forelimb lameness occurs.

Diagnosis is confirmed radiologically (see Figure 53-1, A) (Figure 53-9). Most fractures are detectable on lateral-lateral images, although ventrodorsal images give additional information about the extent of the fractures, especially those involving the atlas or axis. Lateral oblique images can also be helpful in selected horses. Care should be taken not to confuse physes and separate centers of ossification with fractures.

The prognosis depends on the site and configuration of the fracture(s), the degree of displacement, and hence the likelihood of permanent compression of the spinal cord, either by a displaced fracture or by subsequent callus formation.

Fractures of the atlas and axis, especially through the physis of the separate center of ossification of the dens, are particularly common in foals. The prognosis for complete recovery is fair with conservative management, provided that no evidence of ataxia exists. Usually no treatment is required other than confinement to a box or small pen.

Fractures of the cervical vertebrae in adults more commonly involve the vertebral body or arch in the midneck region (the third to sixth cervical vertebrae) or the synovial articular facets of the more caudal vertebrae (the fifth to seventh cervical vertebrae). Local hemorrhage and edema may result in ataxia, which usually resolves within a few

Fig. 53-9 • Lateral radiographic image of the third to fifth cervical vertebrae of a 9-year-old Dutch Warmblood dressage horse with severe neck pain, stiffness, and incoordination after a fall 12 days previously. The fourth cervical vertebra (C4) has a comminuted, slightly displaced fracture of the dorsal arch. Ataxia resolved within another 14 days, and the horse made a complete functional recovery.

days. Persistence of ataxia warrants a guarded prognosis. Most fractures heal by callus formation, and this may subsequently impinge on the spinal cord, causing later ataxia. A fracture of a vertebral body also may result in damage to the adjacent intervertebral disk and associated ligaments, which subsequently may protrude into the vertebral canal and cause ataxia. Thus in the acute stage giving an accurate prognosis may be difficult. However, many fractures of the vertebral bodies and synovial articulations do heal, and horses may be able to return to athletic function, although residual neck stiffness may be present.

In the acute stage the horse should be confined to box rest. Analgesics may be necessary to control severe pain, but they should be used judiciously to avoid encouraging excessive movement of the neck. The position of the water bucket and manger should be adjusted so that the horse can drink and eat from normal head height. The hay should be fed at a height level with the head, preferably loose, or if in a hay net, a net with large holes, with the hay well shaken first. The horse should not be tied up during the convalescent period in case it pulls back. Reappraising the horse clinically and radiologically every 6 to 8 weeks is helpful. Maximum clinical improvement may not be seen until 6 to 9 months after injury. Selected fractures may require surgical stabilization.⁸

Myeloma

Myeloma is a myeloproliferative disorder that can cause radiolucent lesions in any bone, including the cervical vertebrae, with associated bone pain.^{24,34} Cervical vertebral myeloma was diagnosed in several horses of a wide range of breeds and ages.³⁴ Clinical signs included intermittent pyrexia, severe neck pain and stiffness, episodic forelimb lameness, weight loss, and a variety of other abnormalities. Diagnosis is based on hematological, radiographic, and bone biopsy examinations. Hematological abnormalities include anemia, leukocytosis, neutrophilia, and lymphocytosis. Total protein concentration is elevated greatly.

Protein electrophoresis shows a clinically significant monoclonal peak in the gamma region. Radiological examination of affected bones reveals clearly demarcated lucent zones, usually without a sclerotic rim. Bone biopsy is useful to confirm the diagnosis, but currently no treatment is available and the prognosis is hopeless.

Other Cystlike Lesions in Cervical Vertebrae

Occasionally, single or several well-demarcated radiolucent zones are identified in one or more adjacent vertebrae, associated with profound neck pain, with or without forelimb lameness.³⁵ These lesions have not been proved to be caused by osteomyelitis or myeloma, although a definitive diagnosis has not always been possible by bone biopsy or postmortem examination. One horse with extremely severe neck pain and forelimb lameness had radiolucent zones in the fifth and sixth cervical vertebrae, and bone biopsy revealed accumulation of abnormal plasma cells, but the horse made a most spectacular and complete recovery after exploratory surgery and returned to international show jumping. A show pony had a large cystlike lesion in the fourth cervical vertebra with profound neck pain and left forelimb lameness (Figure 53-10). Postmortem examination revealed a cavity filled with granulation tissue, surrounded by a large area of bone necrosis, but no suggestion of the underlying cause.

Vertebral Osteomyelitis

Cervical vertebral osteomyelitis usually occurs secondary to a systemic disease such as *Rhodococcus equi* infection in foals, *Streptococcus equi* infection (strangles), tuberculosis, or brucellosis; or as an extension of soft tissue infection⁴; or through hematogenous spread. Clinical signs may include pyrexia, neck stiffness or pain, and an abnormal neck posture, poor appetite, and weight loss. Usually leukocytosis, neutrophilia, and hyperfibrinogenemia are also present. Radiological examination of the cervical vertebrae may reveal focal radiolucent zones, with or without surrounding increased radiopacity, in one or more vertebrae.⁴ Useful diagnostic tests include bone biopsy, tuberculosis skin testing, and measurement of *Brucella* titers. Aggressive antimicrobial treatment may result in amelioration of clinical signs, but the prognosis is guarded.

Jugular Vein Thrombophlebitis

Thrombophlebitis of the jugular vein is a common condition associated with intravenous injection and chemical irritation, mechanical trauma to the vessel wall through catheterization, or a coagulation disorder. The vein feels abnormally hard, but unless the left and right sides are affected, the thrombus is infected, or thromboemboli settle elsewhere, usually no other clinical signs are apparent.

Occasionally a long length of the jugular vein is occluded by a thrombus in which bacteria are seeded, resulting in infectious thrombophlebitis. Clinical signs include neck stiffness and pain, localized heat and swelling, and pyrexia. If a long length of the vessel is involved, ipsilateral swelling of the head may occur. Diagnosis is based on clinical signs and ultrasonography.⁶ A heterogeneous, cavitating echogenic thrombus can be seen in the jugular vein. Usually leukocytosis, neutrophilia, and hyperfibrinogenemia are present. A horse with a localized, small infected thrombus usually responds well to prolonged

Fig. 53-10 • A, A 13-year-old show pony with exquisite neck pain, worse on the left side, and episodic severe left forelimb lameness. The pony showed a shortened cranial phase of the stride at the walk, and periodically the pony stopped, holding the limb in a semiflexed position, and was reluctant to move forward. There was hyperesthesia of the caudal half of the left side of the neck. **B**, Lateral-lateral radiographic image of the midneck region of the same pony. A large radiolucent zone (*arrow*) is visible in the caudal aspect of the vertebral body of the fourth cervical vertebra (C4). There is a loss of continuity of the caudal cortex.

systemic antimicrobial therapy. Injection of antimicrobial drugs into the thrombus may be indicated if there is inadequate response to systemic therapy. The lesion should be monitored clinically and ultrasonographically. With more extensive lesions or associated toxemia or bacteremia, surgical ligation and removal of the vein may be required, combined with systemic antimicrobial treatment.

Inadvertent perivascular injection of an irritant drug, such as phenylbutazone, may result in the rapid development of localized pain and swelling caused by chemical irritation. This may be followed by an aggressive inflammatory response, leading to sloughing of the skin. If perivascular injection is suspected, then the area should be treated by local infiltration with a balanced electrolyte solution (1 L) to dilute the drug, combined with local anesthetic solution (10 to 20 mL mepivacaine) to reduce pain. Periodic hot packing seems to ameliorate clinical signs. If the condition is initially untreated and local tissue necrosis supervenes, a skin slough is almost inevitable, and prophylactic antimicrobial therapy may be indicated.

Neck Stiffness and Cervical Vertebral Mobilization under General Anesthesia

Assessment of neck flexibility has been described (see page 607). Restricted neck mobility associated with other clinical signs suggestive of neck pain, for example, reluctance to accept the bit, may be an indication for cervical vertebral

mobilization under general anesthesia (see Chapter 95). The aim is to assist in restoring normal function to soft tissue components of joints. However, horses with preexisting osteoarthritic changes are unlikely to respond. Repeated or maintained end-of-range passive joint movements may lower intraarticular pressure, inhibit reflex muscle contraction around a joint, and reduce muscle tension on the periarticular soft tissues and thus relieve pain. The manipulations are performed with the horse in left and right lateral recumbency under general anesthesia. Nine manipulations are performed in sequence to include extension of the head and neck, extension with rotation to the left and then to the right, rotation of the head to the left and to the right, flexion of the neck to the left and to the right, and flexion and rotation in each direction. For each maneuver the head and neck are moved to a position at the end of the resistance-free range. Constant pressure then is applied so that movement through the stiff and reduced range can be initiated. The pressure then is maintained until the joints and associated soft tissues move through the range of resistance. When movement ceases, a new end range is established and pressure is released. The maneuver may then be repeated. After treatment, horses are rested for 5 days and then start light work. Clinical improvement usually is appreciable within 2 weeks.³⁶ Repeated treatment may be necessary in selected horses. Occasionally, clinical signs deteriorate after treatment.

Developmental Orthopedic Disease and Lameness

Chapter 54

Pathogenesis of Osteochondrosis

Janet Douglas

OSTEOCHONDROSIS: DEFINITIONS AND TERMINOLOGY

Equine osteochondrosis (OC) is characterized by focal failures of endochondral ossification that typically occur in well-defined predilection sites. Lesions that result from external trauma or infection are not generally regarded as OC.^{1,2} The thickened, retained growth cartilage that characterizes typical lesions (Figure 54-1) in the articular-epiphyseal cartilage complex (AECC) may be complicated by development of fissures that extend from the deepest layers of the lesion to the articular surface. Cartilaginous or osteochondral fragments may then detach from the parent bone, forming intraarticular fragments.³ Once lesions extend to the articular surface, thereby causing inflammation of the joint, the condition may be referred to as *osteochondritis*.^{4,5} The term *osteochondritis dissecans* (OCD) is usually reserved for lesions in which a dissecting flap of tissue is present (Figure 54-2).³ Although it has been proposed that the term *dyschondroplasia* should be used in place of OC,^{3,6} the term OC remains in widespread use and is used in this chapter to refer to the primary lesion. *Dyschondroplasia* is used only when referring to work by authors who prefer this term. A condition similar to equine OC occurs in a number of other animal species, as well as in people.¹

ENDOCHONDRAL OSSIFICATION

Endochondral ossification is the process by which growing cartilage is systematically replaced by bone to form the growing skeleton.⁷ This process occurs at three main sites: the physis, the epiphysis, and the cuboidal bones of the carpus and tarsus. Chondrocytes in the physis can be divided into a series of layers or zones (Figure 54-3). The zone farthest from the metaphysis is the resting or reserve zone. Adjacent to this is the proliferative zone, in which chondrocytes divide. These cells progress to the hypertrophic zone, in which they enlarge and form ordered columns. During this stage the chondrocytes become

surrounded by extracellular matrix that gradually becomes mineralized in the zone of provisional calcification. The chondrocyte columns are then invaded by metaphyseal blood vessels, and bone forms on the residual columns of calcified cartilage. This mixture of calcified cartilage and immature bone (primary spongiosa) is then gradually remodeled to produce the mature bone of the metaphysis.⁷ Endochondral ossification, which continues throughout the period of growth, also occurs in the AECC at the ends of long bones (Figure 54-4).⁸ The chondrocytes of the AECC that are closest to the articular surface produce articular cartilage, whereas those cells closer to the epiphysis participate in endochondral ossification in the same manner as occurs in the physis. It is generally accepted that the growth cartilages of both the physis and the AECC are susceptible to OC.^{1,3,8-11}

CHARACTERISTICS OF OSTEOCHONDROSIS

Equine OC characteristically manifests as one or two lesions that occur in known predilection sites. In this so-called “typical pattern” of the disease, lesions are often bilaterally symmetrical, although only one lesion may cause clinical signs.¹² The femoropatellar (lateral and medial femoral trochlear ridges, lateral facet of patella), tarsocrural (cranial aspect of the intermediate ridge and medial malleolus of the distal aspect of the tibia, lateral and medial trochlear ridges of the talus), scapulohumeral (glenoid fossa and humeral head), and metacarpophalangeal and metatarsophalangeal joints (midsagittal ridge and condyles of the third metacarpal or metatarsal bone) are affected most commonly. OC of the elbow, hip, and cervical vertebral joints has also been described,^{12,13} but lesions in these sites are less common and the etiology is more controversial.¹² This typical pattern of OC contrasts with that of the atypical pattern in which animals show numerous articular (and sometimes physeal) lesions.^{12,14} Predilection and nonpredilection sites may be affected in these horses, and bilaterally symmetrical lesions are absent or infrequent. A third pattern of lesion distribution, the mixed pattern, describes horses in which both typical and atypical lesions are present.¹⁴

OC may manifest very early in life. For example, lesions of the cranial aspect of the intermediate ridge of the tibia have been identified in foals that are less than 1 month old.¹⁵⁻¹⁷ Lesions of the lateral trochlear ridge of the femur may appear later (3 to 4 months of age),¹⁷ but lesions at this site, on the medial femoral condyle, and in the tarsocrural and fetlock joints all develop before approximately 7 or 8 months of age.^{18,19} The studies from which these conclusions were drawn were conducted in a range of breeds. In contrast, recent radiological data suggest that the

prevalence of OC may increase substantially after approximately 1 year of age in South German Coldbloods.²⁰ Further work is necessary to establish whether there are breed differences in the timing of lesion development.

It is important to realize that most osteochondral lesions identified radiologically in young horses heal without intervention^{17,21-23} and that lesions that lead to clinical signs represent only a small fraction of the total. Thus many of the lesions identified in postmortem studies would never have become clinically relevant and may not even be evident radiologically. The age at which lesions are capable of repair appears to depend on the joint involved. A longitudinal study involving Dutch Warmbloods determined that OC lesions of the hock (the cranial aspect of the intermediate ridge of the tibia and the lateral trochlear ridge of the talus) that were still present at 5 months of age never regressed.¹⁷ Five months was thus designated as the “age of no return” for tarsocrural lesions. In contrast, lesions of the lateral trochlear ridge of the femur did not become permanent until the animal was 8 months of age.¹⁷

The features of equine OC lesions were reported as early as 1947.⁹ Since then the gross and histological characteristics of the condition have been described and defined by numerous authors. Early descriptions characterized OC as a lack of chondrocyte differentiation that prevented provisional calcification of the matrix and invasion of the cartilage by blood vessels.³ Necrosis was described as a secondary change.³ A more recent histological study that examined AECC samples from the lateral trochlear ridge of the femur of horses ranging in age from 270 days' gestation to 4 years defined OC ("dyschondroplasia") as the presence of cartilage cores (i.e., cartilage extending into subchondral bone).²⁴ This study identified two types of lesion that could be differentiated on the basis of type VI collagen immunoreactivity. However, both types showed evidence of chondrocyte clusters and chondronecrosis. Lesions of one type (group A) showed disruption of the normal sequential transition of chondrocytes through the stages of proliferation and maturation and were characterized by accumulation of large numbers of small, rounded chondrocytes, apparently arrested at the prehypertrophic stage. In contrast,

Fig. 54-5 • Chondrocyte clusters (arrows) surrounding an area of necrotic cartilage. Toluidine blue stain. (Courtesy Frances Henson, Department of Veterinary Medicine, University of Cambridge, Cambridge, United Kingdom.)

group B lesions showed alteration in the staining pattern of mineralized cartilage and adjacent subchondral bone and complete absence of invading capillaries into newly formed bone.^{24,25} Differentiation of lesions into subcategories was not reported in a recent histological study in which necrosis of growth cartilage was described as a common feature of OC lesions.¹⁵ This study was carried out using material from the distal tibiae of foals that were all 5 months old or younger (the age range during which the disease is initiated at this site).¹⁷ The results suggested that chondrocyte necrosis precedes matrix change (identified histologically as relative eosinophilia and pallor in hematoxylin-eosin-stained sections and as pallor in toluidine blue-stained sections), delayed ossification, and fissure formation. Moreover, these authors considered chondrocyte clusters to be a sign of attempted repair rather than a primary change.¹⁵

It is obvious from this short summary that histological definitions and descriptions of OC vary, making accurate identification of lesions difficult.²⁴ Even chondrocyte clusters (Figure 54-5), considered by many to be one of the most consistent findings in OC lesions,^{24,26} are not pathognomonic for the disease,^{15,24} and, unless used to define the condition, necrosis is not a universal finding.^{25,27} It is thus not surprising that the relevance to OC of some of the lesions studied has been questioned.²⁸ The matter is complicated further by the limited repertoire of responses that bone and cartilage can mount to injury and developmental abnormalities¹² and by the fact that many lesions are not identified until they have reached the chronic stage. The features of such chronic lesions may represent the results of secondary change and attempted repair, rather than primary osteochondrotic change. The results of studies based on such lesions may thus be misleading. This situation has resulted in a wide-ranging, heterogeneous, and somewhat confusing body of literature, in which equine OC has been ascribed to genetic, dietary, endocrine, biomechanical, traumatic, ischemic, and toxic causes.^{12,18,26,29-33}

RELATIONSHIP AMONG PHYSEAL DYSPLASIA (PHYSITIS), SUBCHONDRAL BONE CYSTS, AND OSTEOCHONDROSIS

The relationship between OC and physeal dysplasia (physitis or epiphysitis) is poorly defined. Retained cartilage has long been regarded as a possible cause of physeal dysplasia,^{16,34} and OC lesions of the physis have been described in clinically affected horses (thickened and irregular metaphyseal growth cartilage)^{5,10} and in foals with experimentally induced dyschondroplasia (retained cartilage cores).^{26,35} If OC truly is a generalized or multifocal disturbance of endochondral ossification, it would seem logical that metaphyseal growth cartilage has the potential for involvement. However, some have questioned whether articular and physeal lesions have the same cause and have proposed that physitis be regarded as a manifestation of developmental orthopedic disease but not of OC.¹² Moreover, the results of a recent study suggest that many enlargements of the distal aspect of the third metacarpal and metatarsal bones, including those with evidence of increased metaphyseal cartilage thickness, represent physiological remodeling rather than a pathological process.³⁶ The role of OC in the pathogenesis of equine physeal dysplasia thus remains unclear. However, it should be noted that a similar pathogenic mechanism (failure of blood supply to growth cartilage) has been proposed for both articular OC and physeal lesions in pigs.¹ Physitis is covered in more detail in Chapter 57 and is not discussed further here.

The relationship among OC, subchondral bone cysts, and osseous cystlike lesions is also controversial. In contrast to OCD lesions, which are most commonly found on the nonloaded margins of high-motion joints, bone cysts typically occur in the central, loaded areas of joints.² Originally interpreted as a manifestation of retained cartilage of the AECC,^{10,37-39} many cysts are now thought to be traumatic in origin.^{40,41} This proposed cause was demonstrated experimentally by the successful induction of cysts in the medial femoral condyle (a predilection site) after creation of a linear slit in the articular cartilage followed by normal weight bearing.⁴² OC may thus be only one of several possible causative mechanisms,^{12,40,43} and cysts may result from a number of nonspecific articular injuries sustained at a load-bearing site.¹²

PROPOSED CAUSATIVE FACTORS

Numerous studies aimed at determining the cause and pathogenesis of equine OC have been performed, and many of the factors investigated have been shown to influence the incidence of osteochondral lesions. However, because OC cannot yet be diagnosed on anything other than morphological grounds, it is unclear whether the lesions induced by some of these potential causative factors are the same as those that occur under "natural" conditions. A pertinent example is low copper intake, which has been shown to induce osteochondral lesions⁴⁴ but which is not believed to be a causative factor in most horses with naturally occurring OC.^{1,45}

It is generally accepted that equine OC has a multifactorial cause.^{1,25,45} This renders more difficult the task of unraveling the pathogenesis of the disease. Further complications

are introduced by the presence of interrelationships among a number of proposed causative factors. For example, a horse's growth rate may be affected by its genetic background,⁴⁶ its plane of nutrition,⁴⁷ and possibly also by its hormonal response to carbohydrate intake,⁴⁸ all factors that have been implicated in the pathogenesis of OC.

Another topic that requires clarification is the balance between generalized or systemic and local factors. OC has historically been described as a generalized failure of endochondral ossification.¹⁶ However, the propensity for lesions to occur in a small number of bilaterally symmetrical predilection sites argues strongly that local factors are important in the cause. It remains to be determined whether lesions can be induced solely by these local factors or whether the presence of an underlying generalized disorder (e.g., biomechanically or biochemically inferior tissue) is a prerequisite for lesion development. The following discussion summarizes major findings relating to the pathogenesis of equine OC.

Involvement of Cartilage Canals

There has been much interest recently in the role of cartilage canals in the pathogenesis of equine OC. Cartilage canals are channels that invade the epiphyseal growth cartilage from the surrounding perichondrial plexus.⁴⁹ The arterioles, venules, and capillaries that they contain assist in the nutrition of epiphyseal cartilage, much of which is too far from synovial fluid to obtain nutrients by diffusion.¹ Under normal circumstances the cartilage canals become obliterated in a regionally staggered sequence^{29,49} as endochondral ossification (and therefore growth) ceases. Studies performed to date have found no evidence of cartilage canals in foals after approximately 6 or 7 months of age.^{18,27,50} There is an apparent anatomical association between prolonged dependence of cartilage on a vascular supply and predisposition to OC.²⁹

A number of investigations have highlighted an association between the presence of cartilage canals and development of OC. However, the proposed pathogenic mechanism differs among studies. A report published in 1995 that involved examination of tissue from 35 horses younger than 18 months of age found that cartilage canals containing patent blood vessels were present in all samples taken from OC predilection and nonpredilection sites in foals younger than 3 weeks of age.¹⁸ Overall, 34% of the horses had lesions of OC in the medial femoral condyle, lateral femoral trochlear ridge, and/or distal aspect of the tibia, and the prevalence rose to 56% in horses 3 weeks to 5 months of age. All the lesions seen in this age group (3 weeks to 5 months) were associated with necrotic cartilage canal blood vessels. Lesions found in horses 7 months of age and older had extensive involvement of subchondral bone and bone marrow and were considered to be chronic. The authors concluded that OC lesions develop before 7 months of age and that ischemic necrosis of cartilage is involved in the pathogenesis of the condition.¹⁸

This conclusion is supported by the results of more recent work conducted using tissue from the distal tibiae and tarsi of foals 5 months of age or younger.^{15,29,51} From the results of a histopathological study, it was concluded that early OC lesions manifest as areas of cartilage canal and chondrocyte necrosis within the proliferative zone.¹⁵

Fig. 54-6 • Histological section from the intermediate ridge of the tibia of a 3-week-old foal showing an area of chondrocyte necrosis within the proliferative zone (stippled outline) and a band of chondronecrosis within the ossification front (between arrows). Both are associated with necrotic cartilage canals (arrowheads). Toluidine blue stain. (Courtesy Osteochondrosis Research Group at the Equine Clinic, Norwegian School of Veterinary Science, Oslo, Norway.)

As the ossification front advances, these lesions become incorporated in the chondro-osseous junction where the necrotic chondrocytes and altered matrix are believed to represent conditions unfavorable for vascular invasion and replacement by bone (Figure 54-6). Vascular perfusion techniques were used to show that as foals grow the mid-portion of each cartilage canal becomes incorporated into the ossification front.²⁹ Anastomoses then form between canal vessels and subchondral vessels at this point.²⁹ As a result, tissue that is nourished by the vessels in the end of the cartilage canal farthest from the perichondrium comes to be nourished by subchondral vessels. The histological lesions identified were consistently characterized by the presence of necrotic growth cartilage in association with necrotic cartilage canal vessels located at the point where the vessels cross the ossification front, suggesting that the vessels are prone to failure at this point.²⁹ These results are supported by the results of micro-computed tomography analysis.⁵¹

An earlier study proposed a different mechanism for involvement of cartilage canals in the pathogenesis of OC. In this investigation, which involved horses that were in some cases considerably older than those in the previous study (≤ 15 months), nonnecrotic dyschondroplastic lesions were associated with cartilage canals containing patent vessels.²⁷ This finding led the investigators to propose that in some circumstances the presence of cartilage canals may be associated with failure of chondrocytes to hypertrophy and that this may be the initiating lesion. It was suggested that blood vessels within cartilage canals may expose local growth cartilage to any imbalance of systemic hormones (such as that induced by a high-energy diet) and that chronicity of lesions accounted for the difference between these findings²⁷ and those of studies in which necrosis is a dominant feature. It should be noted that proximity of osteochondral lesions to the remnants of cartilage canals has been reported in many studies, but is not a universal finding.⁵²

Body Size and Growth Rate

The widespread anecdotal belief that OC is more prevalent in large horses and those with a rapid growth rate gained support from the results of a Swedish survey involving 77 Standardbred (STB) foals.⁵³ This study reported a positive relationship between radiologically evident OC of the tarsocrural joint and body weight at birth, body weight during the growth period, average daily weight gain, and skeletal frame size. Seven of the eight foals that developed tarsocrural OC were sired by the same stallion, but the relationship among OC, body measurements, and growth rate was still present when affected and unaffected foals by this sire were considered in isolation.

In postmortem studies, positive associations were reported between various measures of body size and number and severity of OC or OC-like lesions in the limbs and cervical vertebrae of 12-month-old animals of various breeds⁴⁷ and between recent average daily weight gain and tarsocrural osteochondral lesions in 5-month-old Thoroughbred (TB) foals.⁵⁴ However, this latter study found no significant association between body weight and the frequency or severity of lesions, a finding that was echoed in a recent study involving Hanoverian foals.⁵⁵

Further evidence for a relationship among OC, body size, and growth rate comes from a study performed in Warmbloods.⁵⁶ Weight and height were measured from birth to 5 or 11 months of age in 43 foals with a presumed genetic predisposition to OC of the femoropatellar or tarsocrural joints. The foals' stifle and hock joints were evaluated radiologically, macroscopically, and histologically. Development of femoropatellar OC was associated with a higher overall rate of weight gain and greater final body weight and height. Moreover, the period during which weight gain of the OC-positive foals was significantly higher than that of the OC-negative foals coincided with the period during which femoropatellar joint lesions become visible radiologically.¹⁷ In contrast to the previously described findings in STBs,⁵³ no relationship existed between tarsocrural OC and body size or growth rate in this population of Dutch Warmbloods.⁵⁶ A similar lack of correlation between surgical OC lesions and body weight has been reported in TBs.⁵⁷

Nutrition

A number of dietary factors have been implicated in the pathogenesis of OC. These include digestible energy, phosphorus, and copper.

Digestible Energy and Protein

The results of a French study have suggested that a high plane of nutrition does not in itself predispose to development of OC, as long as the ration is balanced.⁴⁷ However, a high nutrient intake was implicated in the pathogenesis of OC for many years¹⁰ and the topic has been explored in a number of studies. One landmark trial investigated the effects on skeletal development of feeding 129% of National Research Council (NRC, 1989)⁵⁸ recommendations for digestible energy or 126% of NRC recommendations for crude protein to foals approximately 5 months of age.²⁶ A control group received 100% of NRC recommendations for energy and protein. After 12 to 16 weeks on the experimental diets, all foals were euthanized, growth plates and the growth cartilage of the AECC were examined, and a

definitive diagnosis of dyschondroplasia was made only when a retained core of cartilage was identified histologically. Dyschondroplasia occurred in two of 12 control foals (17%), four of six foals on the high-protein diet (67%), and all 12 foals on the high-energy diet. The lesions in the foals in the high-protein group were minor and were mainly single lesions of the growth plates, with no AECC involvement. No significant difference in incidence occurred between the control and high-protein groups. In contrast, many of the foals in the high-energy group had lesions of the AECC and the growth plates, and the difference in incidence between the control and high-energy groups was significant.

The effects of overfeeding on endochondral ossification within the growth plate have been described. Twelve TB weanlings aged 6 to 8 months were randomly assigned to receive diets containing 70%, 100%, or 130% of the National Research Council recommendations (1978)⁵⁹ for digestible energy and protein.⁶⁰ All diets contained 100% of the recommended levels of calcium and phosphorus. Biopsies of the distal radial physis obtained after 8 months showed that physeal thickness was directly proportional to digestible energy level. Moreover, the physes of the overfed horses showed many features similar to those of OC: the reserve and hypertrophic zones were enlarged, the hypertrophic cartilage had lost its normal columnar organization, and metaphyseal capillaries appeared unable to penetrate this abnormal hypertrophic cartilage. It was concluded that the lesions associated with overfeeding were similar to those caused by hypothyroidism and that the link between dietary excess and OC is mediated by endocrine factors.⁶⁰

Subsequent work showed that ingestion of a high-energy meal is associated with accelerated insulin secretion, decreased thyroxine (T₄) secretion, and accelerated conversion of T₄ to triiodothyronine (T₃).⁶¹ Insulin, T₃, and T₄ play a role in controlling the terminal differentiation of chondrocytes,^{62,63} and it is possible that the transient postprandial hypothyroxemia induced by diets high in energy could adversely affect osteochondral development. Moreover, studies conducted on equine tissue suggest that insulin may promote the survival or depress the differentiation of chondrocytes in growth cartilage, potentially reducing the rate at which cells enter the terminal phases of hypertrophy and leading to accumulation of prehypertrophic chondrocytes.⁶⁴

The possibility of a relationship between abnormal insulin levels and osteochondral lesions is supported by the finding that postprandial plasma glucose and insulin levels are significantly higher in young horses with OC than in unaffected animals,^{57,65} an association that may be mediated, at least in part, by the glycemic index of the feed.⁵⁷ An association between feeds with a high glycemic index and increased plasma levels of insulin-like growth factor I (IGF-I) has been observed during periods of rapid growth.⁶⁶ IGF-I, which is structurally similar to insulin, is primarily involved in the control of growth and differentiation,⁶⁷ including regulation of chondrocyte growth and endochondral ossification.^{64,68} However, recent data show that there is cross-talk between the insulin and IGF-I pathways, and that IGF-I participates in metabolic activities such as promotion of glucose uptake.⁶⁷ The suggestion that a high glycemic index feeding regimen and osteochondrotic risk may be linked via increased IGF-I levels is contradicted by

a study in which OC-positive foals were found to have significantly lower IGF-I activity than those without the disease.⁶⁹ The significance of the IGF-I pathway in the pathogenesis of OC thus remains unclear.

Calcium and Phosphorus

The effects of overfeeding phosphorus (388% of NRC [1989] recommendations), calcium (342%), and both calcium and digestible energy (342% and 129%, respectively) for 16 to 18 weeks was assessed in foals aged 2½ to 6½ months at the start of the study.³⁵ The diets containing excessive phosphorus and calcium provided 100% of NRC recommendations for digestible energy. Histologically confirmed dyschondroplastic lesions were found in numerous joints and growth plates in two control foals (17%), five foals fed excess phosphorus (83%), two foals fed excess calcium (33%), and six foals fed excess digestible energy and calcium (100%). The lesions were more numerous and severe in the foals fed high-phosphorus or high-digestible energy and high-calcium diets than in the control foals or those fed high-calcium diets only. Dyschondroplasia is thus not induced by diets high in calcium and is not alleviated by excessive calcium in foals fed excessive energy. The apparent association between excessive dietary phosphorus and abnormal endochondral ossification may be mediated by acidosis³⁵ or by osteoporosis-induced weakening of the subchondral bone plate.⁴⁵

Copper

Copper is a necessary cofactor of lysyl oxidase, the enzyme that catalyzes the oxidative deamination of lysine and hydroxylysine residues to their corresponding aldehydes. This is a necessary step in the formation of pyridinoline cross-links in collagen and elastin. Low-copper diets have been associated with an increase in the soluble fraction of articular collagen, reduced collagen cross-linking of cartilage and bone, and an increased incidence of osteochondral lesions in growing foals.^{44,70} A plausible mechanistic link thus exists between low copper levels and the development of OC, via the formation of biomechanically weak cartilage and bone. However, the clinical significance of this proposed pathogenic mechanism in the cause of naturally occurring OC remains unclear.

Several early studies showed an association between primary or secondary copper deficiency and equine osteochondral lesions.⁷⁰⁻⁷² However, the lesions reported—which included intrachondral splitting through the hypertrophic zone and denudation of subchondral bone—were generally much more widespread and severe than typically occur under field conditions.⁷⁰⁻⁷² Moreover, retention of cartilage was not a major pathological feature.⁷⁰ This link between copper deficiency and development of osteochondral lesions prompted investigations into the effects on equine skeletal development of copper supplementation during late gestation and the early growing period. In one such study, 21 pregnant mares were assigned to a control group (13 ppm dietary copper) or a supplemented group (32 ppm) during the last 3 to 6 months of pregnancy and the first 3 months of lactation.³² The foals were subsequently fed diets containing 15 ppm (control) or 55 ppm (supplemented) copper for up to 6 months. The copper content of the control foals' diet was close to NRC recommendations. OC was defined as thickening of cartilage within the physis or

AECC. Compared with the supplemented foals, 6-month-old control foals had nearly twice as many lesions in the physes and more than five times as many in the AECC. The most notable lesions in the control group were cartilage thickening and separation of the cranial aspect of the intermediate ridge of the tibia.³²

A separate study investigated the effects of feeding diets containing 8 and 25 ppm copper to 3-month-old foals for 6 months.⁴⁴ Cartilage and bone lesions were rare in the foals fed 25 ppm copper. In contrast, the majority of the foals fed 8 ppm copper were severely affected with numerous lesions. Cartilaginous flaps and cartilage thinning, erosion, and eburnation comprised the majority of the lesions, many of which were associated with microfractures within the physes and primary spongiosa of the long bones and cervical vertebrae. Biochemical analysis of tissues from four low-copper-diet foals with OCD-like lesions revealed significantly fewer pyridinoline cross-links in articular cartilage, physeal cartilage, and bone than in tissues from a group of six foals (four supplemented, two on low-copper diets) with no lesions. This study thus demonstrated a link among low dietary copper, inferior collagen quality, and OCD-like lesions.⁴⁴

The pathological condition induced in these two studies by dietary copper levels of 8 and 15 ppm appeared similar to naturally occurring OC grossly, radiologically, and in many cases histologically.^{32,44} However, the relevance to the field situation of the lesions recorded remains unknown. Foals fed the lower amount of dietary copper in these studies typically had numerous lesions, many of which were present in the cervical vertebrae.^{32,44} This lesion distribution would thus be described as atypical.^{12,14} Moreover, it is evident that relatively high levels of dietary copper (25 and 55 ppm) do not completely prevent osteochondral lesions,^{32,44} and that relatively low levels (4 to 11 ppm) do not always result in foals with numerous osteochondral abnormalities.^{26,52,73} Supplementation of foals' diets with copper is thus not a panacea, nor is it always effective.⁷³ Provision of copper supplements to pregnant mares has also generally been unsuccessful in reducing the incidence of osteochondral lesions at 5 to 6 months of age,^{52,54} although one study did show a positive effect.⁷³

Hereditiy

Heritability studies of equine OC have been completed in a number of breeds. The proportion of the total variation

in incidence attributed to genetic factors is expressed as the heritability coefficient, and values of up to 0.52 have been reported for OC of the hock (Table 54-1).^{33,74-77} Although the standard errors are in some studies substantial and the range of heritability coefficients reported is quite wide (a factor that may be attributed, in part, to variation in the mathematical approaches used),^{75,77} these findings suggest that at least some manifestations of OC have a genetic component.

Recent genome-wide searches for markers associated with OC have identified significant quantitative trait loci on a number of equine chromosomes in Hanoverians and South German Coldbloods.^{78,79} Further study has revealed a significant association between a single nucleotide polymorphism in the *AOAH* gene and fetlock OC in South German Coldbloods,⁸⁰ but a role in osteochondral development or repair for the protein encoded by this gene (acyl-oxyacyl hydrolase) has not been identified.

In spite of the success of these early genomic studies, it remains likely that OC is a polygenic disorder⁸¹ that develops from the superimposition of environmental factors on a susceptible genetic background. Moreover, genetic factors may influence the development of disease either directly or via influences on other factors that appear to be associated with OC such as conformation, growth rate, and the hormonal response to ingestion of food.^{53,56,57,65} Analysis of large numbers of genotypes will therefore be required for successful identification of the genes involved,⁸² and identification of a simple set of genetic markers is a goal that may well prove elusive.

An alternative strategy for reducing the incidence of OC is to exclude affected mares and stallions from breeding programs. The results of genomic and heritability studies suggest that OC lesions at different anatomical sites may be genetically related,^{75,78} and this raises the possibility that it may be possible to reduce the overall incidence of the disease by such a strategy of selective breeding. The results of mathematical modeling suggest that the incidence of OC in Maremmano horses could be reduced from 16% to 2% over five generations by active selection of both stallions and mares free of the disease.⁷⁷ Researchers who simulated the effects of various selection strategies in Dutch Warmbloods came to a similar conclusion,⁸³ estimating that the incidence of OC would decrease from 25% to 13% over 50 years (2.4% reduction per generation) as a result of two alternative strategies: (1) active selection for

TABLE 54-1

Incidence and Heritability of Osteochondrosis Lesions

SITE OF LESION	BREED	RANGE OF INCIDENCE AMONG PROGENY GROUPS (%)	HERITABILITY COEFFICIENT* (MEAN ± SE)	REFERENCE
Hock	Standardbred	3.4 to 30	0.26 ± 0.14	Schougaard et al, 1990 ⁷⁴
Hock	Standardbred	0 to 24	0.24 ± 0.19 to 0.27 ± 0.08	Philippson et al, 1993 ³³
Hock	South German Coldblood	—	0.04 ± 0.07	Wittwer et al, 2007 ⁷⁵
Hock	Standardbred	0 to 69	0.52	Grøndahl and Dolvik, 1993 ⁷⁶
Fetlock	South German Coldblood	—	0.16 ± 0.16	Wittwer et al, 2007 ⁷⁵

SE, Standard error.

*The heritability coefficient may overestimate the true heritability if there is a high incidence of lesions in one progeny group (as occurred in the study of Grøndahl and Dolvik, 1993⁷⁶).

OC-negative mares and stallions, and (2) progeny testing of stallions. The model output concluded that these strategies were more effective than selection of OC-negative stallions only (17% incidence at 50 years) and no active selection (21%).

Gender

Early reports suggested that the incidence of equine OC was substantially higher in males than females.^{9,10} Nonsignificant relationships between male gender and OC were reported in epidemiological studies in which male/female incidence ratios of 1.6:1 and 1.4:1 were found.^{84,85} However, a controlled study involving Warmbloods reported no gender predisposition for OC of the tarsocrural or femoropatellar joints,⁵⁶ and similar findings were reported in TBs.⁵⁴ In contrast, a study involving South German Coldbloods found a twofold higher risk for OC of the hock and fetlock joints in female horses,²⁰ and a study involving feral horses found typical OC lesions only in fillies.⁸⁶

Exercise

The role of exercise in the pathogenesis of OC has been investigated experimentally, with conflicting results. In one study the incidence of OC was compared in foals subjected to low- and high-exercise regimens from ages 3 to 24 months.⁸⁷ All foals were housed in groups or kept in boxes and allowed paddock exercise for 2 to 4 hours per day. In addition, the low-exercise group received 15 to 45 minutes of walking exercise per day. The high-exercise group received 15 to 45 minutes of walking and trotting, plus eight to 20 gallop sprints of short duration (10 to 15 seconds). At the end of the study, hock and stifle joints were examined clinically and radiologically. OC was detected in only three (6%) of the 50 foals in the high-exercise group, but in 13 (20%) of the 66 foals in the low-exercise group, demonstrating a significant protective effect of high-intensity, short-duration exercise on the incidence of OC.

These findings were not supported by the results of a subsequent extensive investigation into the effects of exercise on musculoskeletal development. Forty-three foals with a presumed genetic predisposition to OC of the femoropatellar or tarsocrural joints were subjected to one of three exercise regimens: pasture exercise only, confinement to a box stall, and confinement to a box stall with an increasing number of gallop sprints.²³ These exercise regimens were imposed from 1 week of age to 5 months, and the incidence of OC, including subchondral bone cysts, was determined at postmortem examination in a subset of the foals at 5 months of age (eight per group). The remaining foals were subjected to the same light exercise regimen for an additional 6 months before euthanasia at 11 months of age. Lesions were found in all 5-month-old foals.²³ Frequency was highest in the tarsocrural joints (1.9 lesions per foal), with a lower incidence in the femoropatellar or femorotibial (1.0), cervical intervertebral (1.0), and metatarsophalangeal joints (0.6). Exercise did not influence the number of lesions, although there was a tendency for lesions to be more severe in the box-rested foals. Exercise also appeared to influence the type and distribution of lesions within the stifle joint: the foals subjected to box rest were more likely to develop subchondral bone cysts (femoral condyles), whereas the trained foals tended to develop OC or OCD lesions (lateral trochlear ridge of the

femur). This difference suggests an effect of mechanical loading on lesion development because the lateral trochlear ridge is loaded by the patella during exercise,¹² and subchondral bone cysts tend to develop at the point of maximum load bearing during the support phase of the stride.^{23,40,43} It was concluded that exercise has no role in the pathogenesis of OC, although it may alter the appearance and distribution of lesions.²³ It should be noted that other studies conducted on tissues from these foals suggested that a regimen of box rest supplemented with short bouts of high-intensity exercise (gallop sprints) had deleterious long-term effects on chondrocyte metabolism and viability^{88,89} and cannot be recommended for optimal musculoskeletal development.

Trauma and Biomechanical Force

The roles of trauma and biomechanical force in the pathogenesis of osteochondral lesions are not well established. It is generally agreed that biomechanical forces are responsible for converting an OC lesion into a dissecting OCD lesion,^{5,10,16} although little solid evidence exists to support this assertion. More pertinent is establishment of the roles of trauma and biomechanical force as primary causative factors. The consistent location of typical OC lesions within joints does suggest involvement of physical factors in the pathogenesis.⁹⁰ It has been proposed that physeal dysplasia could result from excessive force on normal tissues or from the superimposition of normal force on structurally deficient tissues,³⁴ and a similar hypothesis has been suggested for the development of articular OC.^{14,28} Many of the factors discussed previously could lead to generation of abnormal skeletal tissues, and abnormally high forces could result from excessive or inappropriate exercise, excessive body weight, or poor conformation.³⁴ A possible relationship between severe outward rotation of the hindlimb and tarsocrural OC was noted in a study of growing STB foals,⁵³ but proof of a causative effect requires further research.

The Role of Enzymes and Signaling Peptides

There is evidence that disturbances in the expression or function of a number of enzymes and/or signaling peptides may be involved in the pathogenesis of OC. Cathepsins and matrix metalloproteinases (MMPs) are proteases that are involved in the degradation of collagen and other extracellular matrix components. Cathepsin B is present in the AECC of normal growing horses, particularly in the hypertrophic zone,^{52,91,92} and is abundant in the chondrocyte clusters that are commonly found in OC lesions.^{52,91,93} Increased MMP activity was identified in OC lesions, particularly in the deep zone adjacent to subchondral bone, around chondrocyte clusters, and in lines that radiate from the deep zone toward the articular surface.⁹⁴ Other alterations in collagen metabolism that have been identified in association with the presence or severity of OC include changes in serum levels of biomarkers of collagen degradation and synthesis, reduced hydroxylysyl pyridinoline cross-linking (unassociated with copper deficiency), and reduced total collagen content of cartilage.⁹⁵⁻⁹⁷

The potential roles of parathyroid hormone-related protein (PTHrP) and Indian hedgehog (Ihh) in the pathogenesis of OC have been evaluated. These signaling molecules, which regulate chondrocyte differentiation and

hypertrophy in growth cartilage via a negative feedback loop,⁹⁸ are expressed at significantly higher levels in osteochondrotic cartilage than in control tissue, and it has been proposed that this may result in retention of prehypertrophic cartilage and delayed endochondral ossification.^{99,100} However, identification of reduced levels of Gli1 (the primary transcription factor for *Ihh*) in diseased cartilage suggests that further work in this area is necessary.¹⁰⁰

Another peptide that may be involved in the pathogenesis of OC is transforming growth factor- β 1 (TGF- β 1), a signaling peptide that is particularly important in controlling mammalian endochondral ossification^{101,102} and that has been shown to stimulate PTHrP expression.^{103,104} Reduced TGF- β 1 expression has been identified in the AECC of the lateral trochlear ridge of the femur in horses with dyschondroplasia at this site, and it was suggested that this may result in cessation of chondrocyte hypertrophy and an accumulation of prehypertrophic chondrocytes.¹⁰⁵ However, the clinical significance of these findings has not been established. In this work, as in all other investigations into the pathogenesis of OC, it is important that distinctions be made between primary and secondary change whenever possible.

Toxic Causes of Osteochondral Lesions

Foals exposed to excessive amounts of zinc and zinc and cadmium in combination have been found to develop

generalized, severe osteochondral lesions.^{31,106-108} The gross lesions described in these reports were characterized by separation of articular cartilage from subchondral bone. The role of cadmium in the pathogenesis of these lesions is unclear.^{31,106,108} However, the effect of excessive dietary zinc is likely to be mediated by secondary copper deficiency.¹⁰⁹ These environmental contaminants are clearly toxic causes of osteochondral lesions and are not considered to be factors in the pathogenesis of naturally occurring OC.

SUMMARY

A range of conditions results in failure of endochondral ossification and retention of cartilage cores at the cartilage-bone interface. However, opinions regarding pathogenesis of OC still differ widely on the major factors involved in the cause of the naturally occurring condition. The situation is complicated by the apparently multifactorial nature of the condition,^{1,5,8,25,45} by the fact that environmental influences and genetic susceptibility apparently combine to determine the final outcome,⁵³ and by the superimposition of secondary changes on primary lesions. However, it is hoped that a renewed focus on the examination of early lesions may allow development of a unified theory on the pathogenesis of the disease.

Chapter 55

The Role of Nutrition in Developmental Orthopedic Disease: Nutritional Management

Joe D. Pagan

Nutrition may play an important role in the pathogenesis of developmental orthopedic disease in horses. Deficiencies, excesses, and imbalances of nutrients may result in an increase in the incidence and severity of phytitis, angular limb deformity, wobbler syndrome (wobbles), and osteochondrosis.

NUTRITIONAL FACTORS AS A CAUSE OF DEVELOPMENTAL ORTHOPEDIC DISEASE

Mineral Deficiencies

A deficiency of minerals, including calcium, phosphorus, copper, and zinc, may lead to developmental orthopedic disease. Most commonly fed cereal grains and forages

contain insufficient quantities of several minerals. A ration of grass hay and oats supplies only 40% and 70% of a weanling's calcium and phosphorus requirements, respectively, and less than 40% of its requirements for copper and zinc (Table 55-1). The best method of diagnosing mineral deficiencies is through ration evaluation. Blood, hair, and hoof analysis is of limited usefulness.

Mineral Excesses

Horses can tolerate fairly high levels of mineral intake, but excesses of calcium, phosphorus, zinc, iodine, fluoride, and heavy metals, such as lead and cadmium, may lead to developmental orthopedic disease (Table 55-2^{1,2}).

Mineral excesses occur because of overfortification or environmental contamination. Massive oversupplementation of calcium (>300% of required amount) may lead to a secondary mineral deficiency by interfering with the absorption of other minerals such as phosphorus, zinc, and iodine. Excessive calcium intake may be compounded by using legume hays as the primary forage source. Iodine and selenium oversupplementation occurs if supplements are fed at inappropriate levels. A ration evaluation is the best way to identify this type of mineral imbalance.

Environmental contamination is a more likely cause of developmental orthopedic disease, because contamination may result in extremely high intakes of potentially toxic minerals. If a farm is experiencing an unusually high incidence of developmental orthopedic disease or if the location and severity of skeletal lesions are abnormal, environmental contamination should be investigated. Blood, feed, and water analysis should be performed. Chemical

analysis of hoof and hair samples may reveal valuable information. Farms that are located near factories or smelters are most at risk, although osteochondrosis caused by zinc-induced copper deficiency has been reported on farms using fence paint containing zinc or galvanized water pipes.

Mineral Imbalances

The ratio of minerals may be as important as the actual amount of individual minerals in the ration. High levels of phosphorus inhibit the absorption of calcium and lead to a deficiency, even if the amount of calcium present is normally adequate. The calcium/phosphorus ratio in the rations of young horses should never be below 1:1 and ideally should be 1.5:1. Too much calcium may affect phosphorus status, particularly if the level of phosphorus is marginal. Calcium/phosphorus ratios greater than 2.5:1 should be avoided if possible. Forage diets with high calcium levels should be supplemented with phosphorus. The zinc/copper ratio should be 3:1 to 4:1.

Dietary Energy Excesses

In the Thoroughbred (TB) industry, large, well-grown yearlings are desirable when offered for sale at public auction because selling price is influenced by body size. Yearlings that sold higher than the median of the session in which they were sold were heavier and taller than yearlings that sold below the session median.³ In addition, TBs that were

heavy and tall as yearlings had the most earnings, graded stakes wins, and grade-1 stakes wins.⁴ Because of the premium price paid for mass, young TBs are often grown rapidly to achieve maximal size. Excessive energy intake can lead to rapid growth and increased body fat, which may predispose young horses to developmental orthopedic disease. A Kentucky study showed that growth rate and body size might increase the incidence of certain types of developmental orthopedic diseases in TB foals.⁵ Yearlings that showed osteochondrosis of the hock and stifle were large at birth, grew rapidly from 3 to 8 months of age, and were heavier than the average population as weanlings.

The source of energy for young horses also may be important, because hyperglycemia and hyperinsulinemia have been implicated in the pathogenesis of osteochondrosis.^{6,7} Foals that experience an exaggerated and sustained increase in circulating glucose or insulin in response to a carbohydrate (grain) meal may be predisposed to develop osteochondrosis.⁸

In a large field trial, 218 TB weanlings (average age 300 ± 40 days, average body weight 300 ± 43 kg) were studied.⁸ A glycemic response test was conducted by feeding a meal that consisted of the weanling's normal concentrate at a level of intake equal to 1.4 g of nonstructural carbohydrate per kilogram of body mass. A single blood sample was collected 120 minutes after feeding to determine glucose and insulin levels. A high glucose and insulin response to a concentrate meal was associated with an increased incidence of osteochondrosis. More research is needed to determine whether the incidence of osteochondrosis can be reduced through feeding foals concentrates that produce low glycemic responses.

RATION EVALUATIONS

The best way to determine whether nutrition is a contributing factor to developmental orthopedic disease is to perform a ration evaluation, which compares the intake of several essential nutrients with the requirements of the horse. Gross deficiencies or excesses of key nutrients then can be identified and corrected. In the past, ration evaluations were time-consuming and cumbersome, because much of the mathematical calculation was done by hand. Fortunately computer programs are now available that make ration evaluations quick and easy to interpret. Kentucky Equine Research (Versailles, Kentucky, United States) has developed an equine ration evaluation program called MicroSteed (www.ker.com).

Types of Evaluations

Ration evaluations can be approached in two ways. One way is to add up what is being fed and compare it with the horse's requirements. This may not be easy because most horse owners do not know exactly what their horses are eating. Alternatively, a new ration may be developed.

Protocol

Every nutrition evaluation should include a description of the horse, definition of nutrient requirements, determination of nutrients in feedstuffs, determination of intake of feedstuffs, calculation of nutrient intake, comparison of intake with requirements, and adjustment of the ration to correct deficiencies or excesses.

Describing the Horse

Different classes of horses have different nutrient requirements, and each class may eat different amounts of forage and grain. Within each class of horse, it is important to know the horse's current body weight, its age and mature body weight if growing, and its rate of body weight gain or loss.

Defining Nutrient Requirements

Ration evaluations are intended to compare a horse's daily nutrient intake with a set of requirements to determine how well the feeding program meets the horse's nutritional needs. The National Research Council (NRC) publishes a set of requirements for horses, but NRC values generally represent *minimum* requirements for most nutrients. These are the levels of intake that are required to prevent the onset of clinical signs associated with frank deficiency. No allowances are included to account for factors that may increase the requirement of a nutrient. The bioavailability of nutrients may be different, and other substances within a ration may interfere with the digestibility or use of a nutrient.

MicroSteed includes two different sets of nutrient requirements—the NRC and Kentucky Equine Research requirements—based on a combination of NRC numbers, research conducted since publication of the most recent NRC recommendations, and experience in the field. The user has the option of selecting NRC or Kentucky Equine Research requirements or adding a custom set of requirements.

NRC values for digestible energy and protein fairly accurately describe the needs of most horses. These two requirements were primarily developed from direct measurements of growth response and energy balance. Other requirements, such as those for calcium and phosphorus, were developed using more theoretical calculations involving estimates of endogenous losses and digestibility. Still others were based on values developed for other species or from single experiments that were far from conclusive. Kentucky Equine Research requirements use values ranging from 1.25 to 3 times those recommended by the NRC for most vitamins and minerals. These nutrient requirements are not absolute, but it is assumed that they adequately reflect horses' needs under a wide range of conditions.

Determining Nutrients in Feedstuffs

The accuracy of evaluating the diet depends on proper sampling of feedstuffs. The feeds should be thoroughly mixed and a representative sample taken. Pelleted feeds are fairly uniform, but sampling is more critical for textured

feeds and home mixes. If an odd nutrient value is encountered, the clinician should look to sampling error as a likely cause.

A hay core can be used to obtain a representative hay sample for analysis. Pasture analysis is more difficult. Should the entire pasture be systematically sampled or only those areas heavily grazed? Horses tend to be spot grazers; therefore sampling the heavily grazed areas is probably best.

When expressing feed intakes and nutrient composition, air dry values for hay and grain and 100% dry matter values for pasture are used, because hay and grain intakes actually are measured as fed, and pasture intakes tend to be estimated. The moisture content of the pasture is not relevant to the evaluation and only complicates intake calculations.

A number of commercial laboratories analyze forages and feeds. For a typical ration evaluation for young growing horses, the following nutrients should be analyzed or calculated for each forage and concentrate: digestible energy (megacalories [Mcal] or megajoules [MJ], typically estimated), crude protein (percent), lysine (percent, typically estimated), acid or neutral detergent fiber (percent), calcium (percent), phosphorus (percent), zinc (percent), copper (percent), and manganese (percent).

These nutrients usually are included on a standard panel analysis at a reasonable cost. Other minerals, such as selenium and iodine, usually are analyzed separately, and analysis can be expensive. Selenium and iodine are not essential for evaluations that focus on identifying nutritional causes of developmental orthopedic disease.

Determining Intake of Feedstuffs

A common flaw in many ration evaluations is measuring intake inaccurately. A weighing scale should be used to measure the amount of grain and hay offered. A certain degree of hay wastage usually occurs, and this should be taken into account when calculating intake. The amount of forage and grain consumed by young horses varies tremendously, depending on geographical location and forage availability. Typically, horses that are raised in tropical environments depend heavily on grain in the ration. Yearlings raised in temperate areas with abundant forage may eat rations that contain 80% forage.

Calculating Nutrient Intake

Determining pasture intake is the most difficult part of conducting a ration evaluation. Two methods usually are employed to estimate pasture intake. The simpler method is arbitrarily to estimate intake at about 1% to 1.5% of a young horse's body weight. The obtained value is approximate, but it is representative of most young horses at pasture for most of the day. A second and more accurate method is to calculate pasture intake energetically, by subtracting the digestible energy intake from all other feedstuffs from the horse's daily energy requirement. Dividing this number by the calculated energy density of the pasture yields daily dry matter intake. For example, a yearling that weighs 330 kg with an average daily gain of 0.55 kg/day should require 20.4 Mcal of digestible energy per day. If that yearling is eating 3.65 kg of sweet feed (10.8 Mcal of digestible energy) and 2 kg of mature alfalfa hay (3.6 Mcal digestible energy), then the yearling must be consuming around 6 Mcal of digestible energy from pasture. Most

grass pastures contain about 2.2 Mcal of digestible energy per kilogram, so this yearling must consume about 2.73 kg of pasture dry matter per day. These intakes can then be used to evaluate the adequacy of the ration for other nutrients. In MicroSteed, pasture intake can be estimated automatically by first entering the other feedstuffs into the ration and then using an estimate key to perform the calculation just described. This method of calculating pasture energy intake works well, provided that the horse actually is consuming the intakes of other feedstuffs and that the correct energy requirements were selected.

Using the method described previously for estimating pasture intake often yields a negative number. If this occurs, then the digestible energy intake of the other feeds is too high, or the calculated energy consumption is too low. Sometimes horse owners report higher intakes of feeds than actually are eaten, which is particularly true for forages, because hay rarely is weighed and large quantities often are wasted. Grain intake can also be overestimated because the coffee can that is used to measure grain does not hold nearly as much grain as it does coffee. At other times the hay and grain intake may be correct, but the horse may be consuming more energy than calculated. Increased energy intake can occur if the horse is expending extra energy to work or keep warm in cold weather, or a young horse may be growing faster than assumed. For example, a yearling needs about 5 kg of additional grain (16.1 Mcal of digestible energy) per kilogram of gain. If average daily gain is higher than assumed, then the horse may be eating significantly more digestible energy than calculated.

Comparing Intake with Requirements

Rarely will the nutrients supplied by a ration exactly match a horse's requirements, and balancing rations with this type of precision is unnecessary. Instead, the key to interpreting a ration evaluation is to identify deficiencies, excesses, or imbalances of nutrients that may affect growth and skeletal soundness. For most nutrients a level of intake in excess of 90% of required is not considered deficient. What is interpreted as excessive varies tremendously among nutrients. For instance, potassium plays only a minor role in skeletal development; a young horse at pasture may consume greater than 300% of its potassium requirement. Most of this potassium comes from the pasture and is perfectly harmless. Even small excesses of other nutrients, such as energy, may play a significant role in the development of skeletal disease. Energy intakes that are 115% of required might trigger mild developmental orthopedic disease, and levels above 130% almost certainly will cause problems in rapidly growing horses.

FEEDING PRACTICES THAT CONTRIBUTE TO DEVELOPMENTAL ORTHOPEDIC DISEASE

Several feeding scenarios may contribute to developmental orthopedic disease. Once identified, most can be corrected easily through adjustments in feed type and intake. Several of the most common mistakes made in feeding young growing horses are explained.

Overfeeding

One of the most common problems of feeding young horses is excessive intake that results in accelerated growth

rate or fattening. Both conditions may contribute to developmental orthopedic disease. Unfortunately, there are no simple rules about how much grain is too much, because total intake of forage and grain determines energy consumption. Large intakes of grain are appropriate if the forage is sparse or of poor quality, as often is the case in tropical environments. For example, grain intakes as high as 2% to 2.5% of body weight may be necessary to sustain reasonable growth in weanlings that have access to no forage other than tropical pasture. Conversely, grain intakes higher than 1% of body weight may be considered excessive when weanlings are raised on lush temperate pasture or have access to high-quality alfalfa hay.

The surest way to document excessive intake is by weighing and using condition scoring in the growing horse. Based on a system developed by Henneke and colleagues,⁹ condition scoring measures fat deposition. Horses are scored from 1 to 9 (1 denoting extreme thinness and 9 indicating obesity). In a Kentucky study, fillies tended to have higher condition scores than colts, and the difference was greatest at 4 months of age (fillies 6.48; colts 6.0). These condition scores are considered moderate to fleshy according to the Henneke scoring system. By 12 months of age the condition scores of the colts and fillies had dropped to 5.3 and 5.4, respectively. Both sexes increased condition score slightly from 14 to 18 months.

Managing the growth in horses becomes a balance between producing a desirable individual for a particular purpose without creating skeletal problems that will reduce a horse's subsequent athletic ability. Growing a foal too slowly results in the risk of it being too small at a particular age or never obtaining optimal mature body size. Therefore it is widely recommended to maintain a steady growth rate by regularly weighing and measuring horses during the growth period.^{1,10}

If growth rate cannot be measured, excessive intake can often be assessed by ration evaluation. For example, a 6-month-old TB weanling (250 kg body mass; 500 kg mature body mass) was being fed 4 kg of a 16% protein sweet feed and 2 kg of alfalfa hay per day, with access to high-quality fall Kentucky pasture. To support a reasonable rate of growth (0.80 kg/day), this weanling required about 17 Mcal of digestible energy per day. The hay and grain intake of this foal alone would supply about 17.5 Mcal of digestible energy, which is slightly above the weanling's requirement. If a reasonable level of pasture intake were included (1% body mass or 2.5 kg dry matter), this weanling would be consuming 135% of its digestible energy requirement, a level likely to cause problems.

To reduce intake, the alfalfa hay should be eliminated, if the pasture is indeed adequate. If hay were needed when the weanling was stalled, grass hay would be more appropriate. Grain intake should be reduced to a level of about 3 kg/day. At this level of grain intake the weanling would need to consume about 3.3 kg of pasture dry matter to support a growth rate of 0.80 kg/day, and the ration would be nicely balanced.

Inappropriate Grain for Forage Provided

Occasionally the concentrate offered to a growing horse is incorrectly fortified to complement the forage that is being fed. The problem occurs particularly when the forage is mostly alfalfa or clover. Most concentrates for young horses

are formulated with levels of minerals and protein needed to balance grass forage.

For example, a 12-month-old yearling (315 kg body mass; 500 kg mature body mass; 0.50 kg/day average daily growth) is raised without access to pasture, and the only forage available is alfalfa hay, which is fed at a level of intake equal to 1.5% of the yearling's body mass (4.72 kg/day). At this level of forage intake, the yearling would require only about 2.5 kg of grain per day. If a typical 14% protein sweet feed that was formulated to balance grass forage were used, the ration would be inappropriate for a number of reasons. Calcium would be 183% of the yearling's requirement, with a calcium/phosphorus ratio of 2.9:1. This would not be a problem except that phosphorus and zinc are marginal in the ration. Because calcium may interfere with the absorption of these minerals, the yearling may be at risk for developmental orthopedic disease from a zinc or phosphorus deficiency. The solution is to feed a concentrate that is more appropriately balanced for legume hay. For example, a 12% protein feed with 0.4% calcium, 0.9% phosphorus, and 180 ppm zinc would be more suitable.

Inadequate Fortification in Grain

The most common reasons for inadequate fortification are using unfortified or underfortified grain mixes, using correctly fortified feeds at levels of intake that are below the manufacturer's recommendation, or using fortified feeds diluted with straight cereal grains. These errors in feeding can be corrected by incorporating a highly fortified grain balancer supplement.

For example, a 6-month-old weanling (200 kg body mass; 400 kg mature body mass; 0.60 kg/day average daily growth) is fed 3 kg/day of a 10% protein sweet feed that is intended for adult horses. To compound matters, the weanling is also fed grass hay, with an estimated intake of 2.3 kg/day. This ration is deficient in protein, calcium, phosphorus, zinc, and copper. The foal would be prone to a rough hair coat and physitis. There are two ways to correct this problem. A properly formulated 14% to 16% protein grain mix with adequate mineral fortification could be used, or 1 kg of a grain balancer pellet could be substituted for 1 kg of the 10% sweet feed. This type of supplement is typically fortified with 25% to 30% protein, 2.5% to 3.0% calcium, 1.75% to 2.0% phosphorus, 125 to 175 ppm copper, and 375 to 475 ppm zinc. This is an extremely useful type of supplement to correct underfortified rations.

FEEDING SYSTEMS TO PREVENT DEVELOPMENTAL ORTHOPEDIC DISEASE

The nutritional requirements of a broodmare can be divided into three stages. Stage one is early pregnancy, from conception through the first 7 months of gestation. Barren mares and pregnant mares without suckling foals fit into this nutritional category. Stage two encompasses the last trimester of pregnancy, from around 7 months of pregnancy through foaling. Stage three is lactation, which generally lasts 5 to 6 months after foaling. The most common mistakes are overfeeding during early pregnancy and underfeeding during lactation.

Early Pregnancy

Proper feeding of a mare during pregnancy requires an understanding of how the fetus develops during gestation. Contrary to popular belief, the fetus does not grow at a constant rate throughout the entire 11 months of pregnancy. The fetus is small during the first 5 months of pregnancy. At 7 months of pregnancy the fetus equals only about 20% of its weight at birth. At this stage in pregnancy the fetus equals less than 2% of the mare's weight, and its nutrient requirements are minuscule compared with the mare's own maintenance requirements (Table 55-3). Therefore the mare can be fed essentially the same as if she were not pregnant. Mare owners often greatly increase feed intake after a mare is pronounced in foal, reasoning that she is now eating for two. Increased feeding is unnecessary and may lead to obesity and foaling difficulties, especially if the mare has access to high-quality pasture.

Late Pregnancy

The fetus begins to develop rapidly after 7 months of pregnancy, and its nutrient requirements become substantially greater than the mare's maintenance requirements; therefore adjustments should be made to the mare's diet. Digestible energy requirements increase about 15% over early pregnancy. Protein and mineral requirements increase to a greater extent, because the fetal tissue being synthesized during this time is high in protein, calcium, and phosphorus. During the last 4 months of pregnancy the fetus and placenta retain about 77 g of protein, 7.5 g of calcium, and 4 g of phosphorus per day. Trace mineral supplementation is also important because the fetus stores iron, zinc, copper, and manganese in its liver for use during the

TABLE 55-3

<i>Expected Feed Consumption by Horses</i>				
HORSE	% OF BODY WEIGHT		% OF DIET	
	FORAGE	CONCENTRATE	FORAGE	CONCENTRATE
Maintenance	1-2	0-1	50-100	0-50
Pregnant mare	1-2	0.3-10	50-85	15-50
Lactating mare (early)	1-2.5	0.5-2	33-85	15-66
Lactating mare (late)	1-2	0.5-1.5	40-80	20-60
Weanling	0.5-1.8	1-2.5	30-65	35-70
Yearling	1-2.5	0.5-2	33-80	20-66
Performance horse	1-2	0.5-2	33-80	20-66

first few months after birth, mare's milk being low in these elements.

New Zealand researchers studied the effect of copper supplementation on the incidence of developmental orthopedic disease in TB foals.¹¹ Pregnant TB mares were divided into copper-supplemented and control groups. Live foals born to each group of mares were also divided into copper-supplemented and control groups. Copper supplementation of mares was associated with a significant reduction in the physitis scores of the foals at 150 days of age. Foals from mares that received no supplementation had a mean physitis score of 6, whereas foals from supplemented mares had a mean score of 3.7. A lower score means less physitis. Copper supplementation of the foals had no significant effect on physitis scores. A significantly lower incidence of articular cartilage lesions occurred in foals from supplemented mares. However, copper supplementation of the foals had no significant effect on physeal cartilage lesions.¹¹ Mares in late pregnancy often are overfed energy in an attempt to supply adequate protein and minerals to the developing foal. If a pregnant mare becomes fat during late pregnancy, she should be switched to a feed that is more concentrated in protein and minerals so that less can be fed per day. This will restrict her energy intake while ensuring that she receives adequate quantities of other key nutrients.

Lactation

A mare's nutrient requirements increase substantially after foaling. During the first 3 months of lactation, mares produce milk at a rate equal to about 3% of body weight per day. This milk is rich in energy, protein, calcium, phosphorus, and vitamins. Therefore the mare should be fed enough grain to meet its greatly increased nutrient requirements. Mares in early lactation usually require 4.5 to 6.5 kg of grain per day, depending on the type and quality of forage they are consuming. This grain mix should be fortified with additional protein, minerals, and vitamins to meet the lactating mare's needs. Trace mineral fortification is not as important for lactating mares, because milk contains low levels of these nutrients, and adding more to the lactating mare's diet does not increase the trace mineral content of the milk. Calcium and phosphorus are the minerals that should be of primary concern during lactation. Grain intake should be increased gradually during the last few weeks of pregnancy so that the mare is consuming nearly the amount that it will require for milk production at foaling. A rapid increase in grain should be avoided at foaling because it could lead to colic or laminitis. Milk production begins to decline after about 3 months of lactation, and grain intake can be reduced to maintain the mare in desirable condition.

Sucklings

If a broodmare has been fed properly during late pregnancy, giving mineral supplements to a suckling is unnecessary until it reaches 90 days of age. At 90 days, moderate amounts of a well-fortified foal feed can be introduced and gradually increased until the suckling is consuming around 0.5 kg of feed per month of age.

Birth month has a significant effect on suckling growth. Kentucky TBs born in the winter (January and February) have been found to be smaller at birth and to grow more

slowly during the first 2 months compared with spring-born foals. These winter-born foals then exhibited rapid daily weight gain at 3 months of age, coinciding with a spring pasture flush.¹² This compensatory growth resulted in there being no difference in body weights between foals born in any birth month at 5 months of age. This rapid growth spurt exhibited in winter-born foals may be undesirable owing to the risk of developmental orthopedic disease, and thus growth of the suckling must be carefully managed.

Furthermore, it is critical that the suckling be accustomed to eating grain before weaning. If the suckling does not become accustomed to eating grain, there is a good chance that its growth rate will decrease dramatically at weaning. When the weanling finally starts eating grain, a compensatory growth spurt occurs that may result in developmental orthopedic disease.

Weanlings

The most critical stage of growth for preventing developmental orthopedic disease is from weaning to 12 months of age, when the skeleton is most vulnerable to disease and when nutrient intake and balance are most important. Weanlings should grow at a moderate rate with adequate mineral supplementation. In temperate regions the contribution of pasture to the diet often is underestimated, leading to excessive growth rates and developmental orthopedic disease.

Yearlings

Once a horse has reached 12 months of age, it is much less likely to develop many forms of developmental orthopedic disease than a younger horse. Many of the lesions that become clinically relevant after this age probably developed at a younger age. Proper nutrient balance remains important for the yearling, and delaying as long as possible the increased energy intakes that are required for sales preparation is best, because the skeleton is less vulnerable to developmental orthopedic disease as a yearling ages. Normally, increasing energy intake 90 days before a sale is enough time to add the extra body condition that often is expected in a sales yearling. Physitis in the carpus is often a major concern for the sales yearling. The level of trace mineral supplementation should remain high to reduce the incidence of physitis in sales yearlings, and a substantial portion of the energy normally supplied from grain should be replaced with fat and fermentable fiber. Sales preparation grain mixes can contain as much as 10% fat. Good sources of fermentable fiber include beet pulp and soy hulls.

NUTRITIONAL MANAGEMENT OF DEVELOPMENTAL ORTHOPEDIC DISEASE

The goal of a feeding program for young horses is to reduce or eliminate the incidence of developmental orthopedic disease. Unfortunately, developmental orthopedic disease still occurs in some foals. Nutritional intervention can help reduce the severity of many forms of developmental orthopedic disease, but not all of the damage resulting from the disease is reversible. However, it is important to alter the feeding programs of foals with developmental orthopedic disease. The type of alteration follows a similar pattern but

depends on the foal's age and the type of developmental orthopedic disease. In almost every instance, energy intake should be reduced while adequate levels of protein and minerals are maintained. The rationale for this type of modification is that skeletal growth should be slowed, but adequate substrate should be available to promote healthy bone development.

Physitis

Grain intake should be restricted to a level supplying around 75% of the foal's normal energy requirement. This restriction, however, should not compromise protein and mineral intake, so a different type of feed formulation may be required. For instance, a 6-month-old weanling (250 kg body mass; 500 kg mature body mass; 0.8 kg average daily growth) on a decent fall pasture would normally consume around 3.5 kg of a 16% protein foal feed. If this foal were to develop physitis, it should be confined and fed grass hay (3 kg/day). Reducing the grain intake to 75% of the foal's normal digestible energy would result in shortages of protein, lysine, calcium, and phosphorus. These shortfalls could be overcome by replacing 1 kg of the 16% sweet feed with a grain balancer pellet. This ration would supply 90%

of the foal's normal protein requirement, along with a good supply of minerals. As the physitis resolves, intake of the 16% grain mix can be slowly increased and the supplement pellet intake slowly decreased, until the foal returns to its normal ration.

Cervical Vertebral Malformation

A feeding program like the one described previously is also appropriate for a horse with cervical vertebral malformation, except that the degree of exercise and energy restriction may be more severe. In this case a feeding program that combines grass hay (2 kg) with a moderate amount of alfalfa hay (2 kg/day) and 1 kg of balancer pellet would result in a reduction in energy intake equal to 65% of normal intake while maintaining adequate levels of protein and mineral intake.

Osteochondrosis

Once a foal has developed osteochondrosis that is severe enough to produce clinical signs, the effect of diet is minimal in solving the existing lesion, but reducing energy intake and body weight while maintaining adequate protein and mineral intake is advised.

Chapter 56

Diagnosis and Management of Osteochondrosis and Osseous Cystlike Lesions

Dean W. Richardson

The pathogenesis of osteochondrosis (OC), palmar or plantar osteochondral fragments of the proximal phalanx, ununited palmar or plantar eminences of the proximal phalanx, subchondral bone cysts, and other osseous cystlike lesions is discussed in Chapters 36, 42, and 54. In this book the term *subchondral bone cyst* is used for large radiolucent areas in the subchondral bone of the medial femoral condyle; these cysts have a consistent pathological structure with a true cellular cyst lining. Osseous cystlike lesions in other locations vary more in structure. This chapter discusses the diagnosis and management of these lesions and other osseous fragments believed to be at least predominantly developmental in origin. The joints most commonly affected include the hock, stifle, fetlock, and shoulder. It is common for matching joints to have lesions but much less common to find OC lesions in different joints. This is consistent with the concept of such lesions occurring during some finite window of vulnerability during development that is specific for a given anatomical location.

Clinical signs of OC range from none to severe lameness. Moderate-to-severe joint effusion often occurs with minimal or no lameness. The clinical signs are not necessarily coincident with the development of the lesion. Most OC lesions are probably formed before 6 months of age, yet most are diagnosed at a later age. Some lesions seen radiologically heal, or they at least become stable enough never to cause a clinically apparent lameness. Lesions in racing Thoroughbreds (TBs) and Standardbreds (STBs) are usually recognized by 2 years of age, but in Warmbloods (WBLs) that are older when they begin training, clinical signs may not be seen until the horse is 5 to 6 years of age or even older. Acute, more severe lameness in older horses occurs occasionally when osteochondritis dissecans (OCD) fragments become loose.

Diagnosis is based on typical clinical signs and radiology. Most OCD flaps in horses have an osseous component and so can be identified using plain radiography. Defects in subchondral bone contours are also easily identified. Radiologically apparent defects in subchondral bone must be interpreted with caution in foals, especially in areas where endochondral ossification occurs later, such as the femoral or talar trochlear ridges and the third metacarpal or metatarsal sagittal ridge. An irregularity in the contour of subchondral bone does *not* mean that an articular defect is necessarily present; the lesion still possibly may heal. Therefore surgical intervention should be delayed until it is clear that either a loose fragment is present or the healing is progressing inadequately. Radiologically apparent lesions must always be interpreted with the clinical signs, because some do not cause clinical signs. If a lesion is identified, the contralateral joint should always be examined radiologically, because bilateral involvement (quadrilateral in the fetlock) is common. The presence of bilateral radiologically apparent lesions in a horse that is unilaterally lame

is not unusual and further emphasizes the need to clinically evaluate the individual horse fully.

Decisions concerning treatment should take into consideration the age of the horse, its intended use, the severity of the lesions and anatomical location, whether the horse is intended for sale through public auction, and, if so, the timing of the sale and the conditions of sale. Prophylactic removal of OCD lesions for economic reasons may be justified in all horses intended for future sale. Most buyers are more willing to purchase horses after an OCD lesion has been removed and the horse has returned to work.

LESIONS IN THE METACARPOPHALANGEAL AND METATARSOPHALANGEAL JOINTS

Osteochondritis Dissecans of the Sagittal Ridge of the Third Metacarpal and Metatarsal Bones

Most foals and yearlings with OCD lesions of the sagittal ridge of the third metacarpal bone (McIII) or third metatarsal bone (MtIII) are not recognized as lame. A variable degree of joint effusion occurs, and the lesions are usually first identified on presale radiographs. Unstable lesions cause lameness and persistent effusion when a horse starts work. Lameness is eliminated by intraarticular or perineural analgesia.

Lesions are more common in the MtIII than in the McIII, but all fetlocks should be examined radiologically if a lesion is recognized in one, using perfectly exposed (or slightly underexposed) flexed lateromedial images (Figure 56-1). Lesions on the dorsoproximal aspect of the sagittal ridge are easiest to recognize, but lesions may occur farther distally or, less commonly, on the palmar or plantar aspect of the sagittal ridge. The latter can also be seen radiologically on the dorsopalmar (plantar) image. The larger fragments extend abaxially along the proximal margin of the articular cartilage under the dorsal synovial fold.

Conservative management should always be considered in horses younger than 18 months old, because lesions can show improvement radiologically and presumably heal. Surgery is indicated in young horses with fetlock effusion and lameness. Young horses treated surgically often do well clinically, but the long-term radiological appearance is inferior to that seen in horses in which the lesions heal spontaneously. Older horses of training age with unstable fragments are treated by arthroscopic debridement. Proximal lesions are technically easy to approach and debride, but lesions that are more distal can be exposed only by slight or moderate flexion of the joint. The arthroscope portal therefore should be made more distal than usual, and a needle should be used to identify a suitable instrument portal. Debriding a sagittal ridge lesion with a portal placed through the extensor tendon directly over the lesion is easiest. Long reaches across a flexed joint may result in undesirable iatrogenic trauma.

The prognosis depends on the size and location of the flap. Probably 90% of horses with typical lesions of the more proximal portion of the sagittal ridge go on to athletic function. Horses with distal lesions in a more weight-bearing location do not do as well as those with flaps at the proximal articular margin, and the radiological appearance does not improve spontaneously as often.

Osseous Cystlike Lesions

Osseous cystlike lesions occur on the weight-bearing surface of the condyles of the McIII and the MtIII. Most occur in the medial condyle and are diagnosed in horses 1 to 2 years of age. The lesions are easy to recognize radiologically (Figure 56-2) and result in obvious lameness, exacerbated by distal limb flexion. Lameness is improved by perineural or intraarticular analgesia. Lameness associated with an osseous cystlike lesion sometimes occurs in foals. At the time of onset of lameness no lesion may be identifiable radiologically, or only a subtle defect in the outline of the subchondral bone may be apparent. However,

Fig. 56-1 • A typical distal sagittal ridge osteochondritis dissecans lesion (arrows) of the third metacarpal bone is seen best on a slightly underexposed flexed lateromedial radiographic image (A) and a well-exposed dorsopalmar image (B).

Fig. 56-2 • A dorsopalmar radiographic image of a metacarpophalangeal joint showing a typical osseous cystlike lesion involving the lateral third metacarpal condyle (arrows).

sequential radiographs obtained over the following 6 to 8 weeks may reveal development of an osseous cystlike lesion. Surgical debridement may be successful,¹ but corticosteroids administered intraarticularly or intralesionally also may result in clinically significant improvement in young horses. Although simple debridement of the McIII and the MtIII osseous cystlike lesions has been reasonably successful, the intensity of loading on the distal aspect of the McIII and the MtIII in athletic horses makes horses with these lesions good candidates for advanced joint resurfacing techniques.

Palmar or Plantar Osteochondral Fragments of the Proximal Phalanx

Osteochondral fragments arising from the proximal palmar or plantar aspect of the proximal phalanx are common radiological findings in WBLs, STBs, and TBs, especially in the hindlimbs. Palmar or plantar osteochondral fragments and ununited palmar or plantar eminences may not cause clinical signs or merely cause mild discomfort at high levels of performance. Assessment of clinical importance and management are discussed in detail in Chapters 36 and 42.

Osteochondral Fragments on the Dorsoproximal Aspect of the Proximal Phalanx

Small, well-rounded osseous opacities on the dorsoproximal aspect of the proximal phalanx are common radiological findings. Most probably occur as small chip fractures of

the developing dorsal rim of the proximal phalanx in foals that subsequently ossify. Whether a true underlying developmental defect (OCD) in this location exists is unclear. Although fragments in this location do not always cause overt lameness, they often are removed in valuable prospective athletic horses and sales horses. Many of these fragments are loosely tethered along the dorsal rim of the proximal phalanx and can cause damage to the distal aspect of the McIII or the MtIII in an intensively exercised horse. Arthroscopic removal is quick and easy, and the prognosis is close to 100% for full function. Horses can be returned to full work within 4 to 6 weeks after removal of these fragments. Often fragments in this location are removed before horses enter training or before a public auction.

LESIONS OF THE PROXIMAL INTERPHALANGEAL JOINT

Lesions in the proximal interphalangeal joint usually cause lameness at a young age, often when the horse is a weanling. Single, discrete, well-defined osseous cystlike lesions or multiple poorly defined radiolucent lesions may be identified, occurring most commonly in the distal condyles of the proximal phalanx (Figure 56-3). Surgical access to most pastern osseous cystlike lesions is difficult, and simple debridement is not usually feasible. Lesions may be advanced when lameness is first recognized, and although occasionally horses spontaneously improve without treatment, horses that are obviously lame usually develop osteoarthritis (OA). Therefore horses that do not respond adequately to corticosteroids administered intraarticularly probably should have an early arthrodesis, especially if a hindlimb is affected. Arthrodesis in young or small horses has been accomplished with one of the well-described techniques using two or three transarticular 5.5-mm screws placed in lag fashion²⁻⁵ or a three-hole narrow plate and two transarticular screws.⁶ In larger horses I currently use two to four transarticular 5.5-mm screws and a central dorsal three-hole locking pastern arthrodesis plate.⁷ The prognosis for athletic function after pastern arthrodesis appears to depend highly on the desired level of activity. Little doubt exists, however, that the prognosis is far superior in a hindlimb than in a forelimb. Most retrospective studies have reported greater than 80% return to athletic function after a hindlimb pastern arthrodesis, but prognosis after a forelimb arthrodesis is likely only around 50%. The intensity of the exercise is probably critical. Few successful elite-level athletic horses (racehorses, upper-level dressage horses, jumping horses) have fused front pastern joints.

Small osteochondral fragments of the proximal interphalangeal joint occur both dorsally and palmarly or plantarly.⁸⁻¹⁰ Like the fragments in the fetlock, many of these appear to be juvenile traumatic injuries that are diagnosed later in life, but a developmental cause cannot be excluded. These fragments do not always cause lameness, so perineural or intraarticular analgesia should be used to confirm the clinical significance of the fragments. The dorsal fragments are relatively straightforward to remove arthroscopically. The palmar fragments require a more technically demanding surgery.⁸

Fig. 56-3 • Lateromedial (*left*) and dorsopalmar (*right*) radiographic images of a proximal interphalangeal joint. The most common manifestation of osteochondrosis in the pastern is an osseous cystlike lesion (*arrows*) in the distal aspect of the condyle of the proximal phalanx.

LESIONS OF THE DISTAL INTERPHALANGEAL JOINT

Well-rounded osteochondral fragments on the dorsoproximal aspect of the extensor process of the distal phalanx are also believed to be developmental in origin. Small fragments are frequently incidental radiological findings, and treatment is not necessary unless associated lameness exists. Lameness should be improved substantially by intraarticular analgesia. Nuclear scintigraphy may help definitive diagnosis. Treatment of horses with lesions associated with lameness is arthroscopic removal of the fragment. The prognosis is excellent (>90%) if the fragment is removed before OA of the distal interphalangeal joint has developed. These fragments are often well embedded in the extensor tendon insertion, so not all fragments adversely affect joint function. As with many other small osteochondral fragments, removal is sometimes done prophylactically.

Osseous cystlike lesions of the distal phalanx can be large and associated with dramatic lameness (Figures 56-4 and 56-5). The pathogenesis may be similar to that of subchondral bone cysts of the distal aspect of the femur. An attempt usually is made to manage such lesions with medications administered intraarticularly. If that is unsuccessful, intralesional corticosteroid injection under fluoroscopic or computed tomographic guidance through the hoof wall is an option. Arthroscopic debridement in young horses with accessible lesions has resulted in good success.¹¹ Extremely large (deep) cysts can be debrided by removing the extensor process in order to provide access.

LESIONS OF THE SCAPULOHUMERAL JOINT

OC of the scapulohumeral joint may involve the glenoid of the scapula or the humeral head. Humeral head lesions

can be solitary, but scapular lesions usually appear with substantial pathological abnormalities of the humeral head in young horses (<2 years old). Lameness can develop insidiously or acutely, presumably after an acute disruption of an unstable osteochondral flap. Recognizing a developing flexural deformity or clubfoot may confuse diagnosis of shoulder lameness in a chronically lame young horse. Occasionally, mild lesions are not recognized until a horse starts training. Lameness is improved by intraarticular analgesia but often is not eliminated. Radiological abnormalities may include poorly defined subchondral radiolucent areas, with or without sclerosis, flattening of the articular surfaces, and modeling of the articular margins, especially the ventral angle of the scapula (see Chapter 40).

Lameness in some young horses improves with rest, and early surgery should not be encouraged in foals younger than 8 to 10 months old unless they are intractably lame. Affected foals should be confined to a stall or small paddock and reexamined clinically and radiologically at 60-day intervals. Intraarticular medication has not been consistently helpful in weanlings and yearlings. The outcome after arthroscopic treatment of OC of the scapulohumeral joint is unpredictable, and lameness can dramatically worsen after surgery. Of 26 potential racehorses, only four (15.4%) started a race, whereas four of six non-racehorses were sound in a recent study of 32 horses that underwent management for osteochondrosis of the scapulohumeral joint.¹² There were no differences between horses managed surgically and those managed conservatively.¹² Radiography may underestimate the severity of lesions, especially those involving the humeral head. It is important to emphasize to an owner before surgery that considerable uncertainty exists about the clinical outcome in any given horse with OC in the shoulder. Solitary osseous cystlike lesions also occur, most commonly in the

Fig. 56-4 • Dorsopalmar (top), lateromedial (middle), and dorsoproximal-palmarodistal oblique (bottom) radiographic images of a foal. There is a large osseous cystlike lesion in the distal phalanx (arrows). Large osseous cystlike lesions of the distal phalanx are difficult management problems because they are relatively inaccessible to surgical debridement.

middle of the distal aspect of the scapula but sometimes in the humeral head (see Chapter 40, Figure 40-14).

OSTEOCHONDROSIS OF THE TARSOCRURAL JOINT

OC of the tarsocrural joint is common in many breeds. Obvious joint capsule distention (bog spavin) may precede recognition of any gait abnormality. Effusion may not be recognized in racehorses examined for poor performance associated with OC, but in show horses with lameness, effusion almost invariably occurs. Horses with radiologically identified lesions are not always lame; therefore diagnosis should be confirmed by intraarticular analgesia or by response to intraarticular medication with corticosteroids. At least four radiographic images should be obtained,

because numerous lesions may be present. If OC is suspected clinically but no lesion is identified radiologically, repeating the dorsoplantar image with slightly different angles of projection is worthwhile, because medial malleolar lesions can be difficult to see (Figure 56-6). Flexed lateromedial images may be necessary to identify lesions involving the plantar aspect of the tarsocrural joint.

OC of the tarsocrural joint is recognized as a common radiological finding in STBs, TBs, and WBLs, but it is not always associated with lameness. Few of the common OC lesions in the hock heal spontaneously after 5 months of age, so surgical removal in young horses, especially sales yearlings, has become commonplace. These lesions are almost always in peripheral, less than completely weight-bearing locations, and removal does not seriously compromise joint function. Prognosis is excellent. However, fragments that cause lameness at a later age are a greater problem because the loose fragments and debris often cause extensive cartilage damage. Older show jumpers in particular may dislodge distal tibial OCD lesions and develop acute clinical signs of effusion and lameness (Figure 56-7).

The cranial aspect of the intermediate ridge of the tibia is the most common site of lesions (Figure 56-8). These lesions rarely cause overt lameness unless major effusion occurs. Arthroscopic removal of the fragment is straightforward and nearly always results in reduction of the lameness and effusion. Lesions may be identified radiologically bilaterally, although only one limb is chronically affected. Loose fragments may become detached in the tarsocrural joint and can become lodged in the communicating proximal intertarsal joint (see Figure 56-8). The opening from the tarsocrural joint into the proximal intertarsal joint at the distal margin of the talar trochlear groove is small or not patent or is small in young foals or weanlings, but as the opening enlarges in older horses, large fragments can move into the proximal intertarsal joint pouches.¹³ If a fragment of bone is found dorsal to (or even on the distal edge of) the central tarsal bone, the fragment is probably one loose in the proximal intertarsal joint that gravitated into that pouch. Fragments associated with lameness should be removed, but it is certainly possible for fragments to localize in this joint and remain stable, causing no clinical signs. It is important to recognize that the fragments in the proximal intertarsal joint usually are not easily seen with an arthroscope and often have to be removed blindly with a rongeurs guided arthroscopically into the joint pouch.

Lesions of the distal aspect of the lateral trochlear ridge of the talus can be enormous and if loose may cause acute severe lameness and substantial effusion (Figure 56-9). This lesion seems to be more common in heavy breeds and STBs. Horses with small, well-attached lesions can be managed conservatively, but any displaced fragment should be removed. The prognosis generally depends on how proximally and axially the lesion extends, but even large lesions can be removed with a good prognosis.

OCD lesions of the medial malleolus of the tibia are easily missed because they are always on the axial rather than the distal (more visible) part of the malleolus (see Figure 56-6). Medial malleolar OCD lesions usually cause more lameness and more effusion than the more common lesions of the cranial aspect of the intermediate ridge of

Fig. 56-5 • Dorsal (left) and sagittal plane magnetic resonance images of a large osseous cystlike lesion of the distal phalanx. There is a large round area of increased signal intensity (*arrows*) in the subchondral bone of the distal phalanx that appears to communicate with the articular surface of the distal interphalangeal joint. Intralesional or intraarticular corticosteroids are often used to treat horses with such lesions, but debridement is feasible using an arthroscopic technique.

Fig. 56-6 • Dorsoplantar (left image) and dorsal 10° lateral-plantaromedial oblique xeroradiographic images of a hock. Identification of osteochondritis dissecans lesions of the medial malleolus requires well-positioned radiographic images. Identifying the lesion on the dorsoplantar image is difficult, but a slight alteration in the obliquity (right image) reveals a large defect (*arrows*).

the tibia. Unless the lesion is unusually large, the prognosis after arthroscopic removal is excellent. Early removal is recommended, because erosive lesions on the medial trochlea of the talus can become severe over time.

Medial trochlear ridge lesions should be interpreted with caution; most distal medial trochlear ridge lesions are incidental radiological findings, and affected horses do not require treatment. Some fragments ostensibly are unstable or somehow irritating because they will be associated with clinical signs (Figure 56-10). Distal medial trochlear ridge lesions may be on the proximal or distal side of the capsular attachment separating the tarsocrural and proximal intertarsal joints. These fragments can reliably be seen only in a lateromedial radiographic image, a radiological finding that is useful to differentiate horses with distal medial trochlear ridge fragments and those with loose fragments

within the proximal intertarsal joint. The fragments wholly within the tarsocrural joint appear to be less stable and more likely to cause lameness. In all horses the decision for surgical removal should be based on a definitive response to intraarticular analgesia. The arthroscopic removal of the tarsocrural lesions is easy and can be done with minimal dissection. Lesions under the capsular attachment often require sharp dissection of the attachment to expose the fragment. Care should always be taken to dissect the minimal amount of soft tissue, especially because the attachments course abaxially.

More centrally positioned, smoothly outlined depressions in the surface of the medial trochlear ridge of the talus are common in large WBLs, draft horses, and draft-cross horses. The subchondral bone architecture is usually normal, and no associated clinical signs are apparent.

Fig. 56-7 • Dorsomedial-plantarolateral oblique radiographic image of the hock of an adult jumper. A defect (*arrowheads*) is evident in the cranial aspect of the intermediate ridge of the tibia. The osteochondritis dissecans fragment displaced from that location was crushed into numerous pieces distributed throughout the tarsocrural joint (*arrows*).

Fig. 56-9 • Dorsomedial-plantarolateral oblique xeroradiographic image of a hock. Osteochondritis dissecans fragments (*arrow*) arising from the distal aspect of the lateral trochlear ridge of the talus are often large, but after surgical removal horses have a good prognosis regardless of size of the lesion.

Fig. 56-8 • Dorsomedial-plantarolateral oblique radiographic image of a hock with a loose osteochondritis dissecans fragment in the proximal intertarsal joint (*open arrow*). This fragment (*open arrow*) “dropped” from the cranial aspect of the intermediate ridge of the tibia, where a larger fragment still resides (*arrows*).

These lesions rarely have an unstable chondral or osteochondral flap that can be removed.

Lateral malleolar fragments are usually traumatic (see Chapter 44) and are only rarely (about 1%) OC lesions. Unlike the traumatic fractures, lateral malleolar OCD lesions have irregular diffuse radiolucency within the

Fig. 56-10 • Lateromedial radiographic image of a hock. Small fragments (*arrows*) along the distal dorsal aspect of the medial trochlear ridge of the talus commonly do not cause lameness, but some are unstable and induce effusion and lameness, particularly fragments on the proximal side of the proximal intertarsal joint capsule.

malleolus instead of a distinctly separated fragment. Arthroscopic debridement of lateral malleolar OCD lesions is difficult because of the extensive collateral ligament attachments that obscure the structure.

Arthroscopic removal of OCD lesions from the hock usually can be followed by a short convalescence and rapid return to work or pasture exercise. Typically a horse is walked in hand for 4 to 6 weeks and then reevaluated. If the effusion has resolved and the horse is jogging soundly, the level of exercise can be increased steadily. Sodium hyaluronan is administered intraarticularly at about the time of suture removal.

Most horses with OCD of the hock have an excellent prognosis, especially if lesions are removed early, before substantial damage to the joint occurs. The specific location of the OCD lesion probably makes less difference than the size, because most hock OCD lesions occur on the peripheral, less than fully weight-bearing surfaces of the bones. Controversy remains about the need to remove all hock OCD lesions, but clearly horses have an excellent (>80%) chance of performing at the expected level after arthroscopic removal of typical lesions.¹⁴⁻¹⁶

The tarsocrural joint appears to be particularly vulnerable to a form of erosive OA that can result in extensive, full-thickness loss of articular cartilage (Figure 56-11). This occurs in the absence of known trauma or radiologically evident lesions, but most horses with the lesion have a history of intraarticularly administered corticosteroids used to manage an effusion. The exact mechanism of this process in the tarsocrural joint is not known, but corticosteroids should be used cautiously to manage effusions of this joint.

LESIONS OF THE STIFLE

Diagnosis and management of OC of the femoropatellar joint, subchondral bone cysts in the medial femoral condyle, and other osseous cystlike lesions in the stifle are discussed in detail in Chapter 46.

Fig. 56-11 • Unlike in most other joints in the horse, full-thickness cartilage erosion of the talus (medial trochlear ridge) (*large arrow*) and distal aspect of the tibia (*DT*) occurs with surprisingly few bony changes such as subchondral lysis or marginal osteophytes. Arthroscopy affords the best means of making the diagnosis. The medial trochlear ridge is nearly devoid of cartilage except for loose and fibrillated cartilage on its summit (*small arrows*).

Chapter 57

Physitis

David R. Ellis

References
on page
1298

Physitis occurs in the horse in three principal forms: infectious physitis and type V and type VI Salter-Harris growth plate injuries.¹ Type V growth plate injury can arise secondary to congenital but persistent angular limb deformities in foals, but these, infections, and type VI injuries are not considered in this chapter. Type V Salter-Harris injuries are considered a manifestation of acquired physitis, one of the group of disorders known as *developmental orthopedic disease*.² The inclusion of acquired physitis under the umbrella of osteochondrosis may be more debatable. Jeffcott³ considered that the condition was better defined as physeal dysplasia, implying a disturbance of endochondral ossification rather than an inflammatory condition. Bramlage⁴ outlined two forms of physitis based on radiological interpretation of the site at which changes were seen. The two forms were those that were seen at the periphery, usually on the medial aspect, and those that were seen in the axial or central section of the growth plate.

Physitis is largely confined to the lighter-boned, faster-growing breeds of horse, particularly Thoroughbreds and

Thoroughbred crossbreeds. Milder physitis is relatively common, and rarely does experienced stud management allow the condition to develop far enough for severe lameness and conformational changes to occur. Only in horses with more extreme or persistent physitis would radiographic examination be undertaken in the United Kingdom. Clinical recognition of enlargement of the growth plate or slight change in conformation usually results in a presumptive diagnosis of physitis and indicates an immediate change of the horse's management as the first line of treatment.

PATHOGENESIS

I consider the pathogenesis of physitis to be consistent with a type V Salter-Harris growth plate injury. This implies a compression lesion that arises medially as a consequence of the greater weight being borne on the medial aspect of the forelimb. Although the medial aspect of the forelimb is the most frequent site, physitis also occurs laterally in a foal with a carpal valgus deformity. Physitis arises at a time in the most active growing phases of young horses, when endochondral ossification is at its peak in the affected physis. It also occurs in the contralateral limb after a chronic lameness, at the fetlock in a younger foal, or at the carpus in older foals and yearlings. For example, I have encountered physitis in the contralateral forelimbs of foals with severe acquired flexural deformity of the distal interphalangeal joint (Figure 57-1). Although physitis may result in an upright conformation of the fetlock joint,

Fig. 57-1 • Dorsopalmar radiographic images of frontal sections of the distal aspect of the third metacarpal bones of a 5-month-old foal with chronic and severe flexural deformity of the left (*L*) distal interphalangeal joint and physitis in the contralateral distal metacarpal physis (*R*). Note the more intense mineralization of the growth plate cartilage and bridging at the medial aspect (to the right of the image) of the right forelimb, typical of Salter-Harris type V growth plate injury.

probably from off-loading the limb to relieve pain, physitis does not cause other flexural deformity.

Physitis is more common on farms that use rigorous or heavy feeding programs. Owners whose stock lives on lush pasture and is supplemented with concentrate feed have a higher incidence of physitis among their horses than those who keep their horses on leaner management. A higher incidence of developmental orthopedic disease is noted in foals and yearlings raised on young (<7 years old) pastures.

I have seen balanced mineral supplementation and withdrawal of concentrates dramatically reduce the incidence of physitis on some farms. Diet and forage analysis can be helpful when high incidence of developmental orthopedic disease is persistent (see Chapter 55), but mineral clearance ratios (creatinine phosphate in particular) are rarely necessary to adjust supplementation. Certain mares may also produce more foals with physitis compared with similarly managed mares, which implies a hereditary predisposition.

CLINICAL SIGNS

Clinical physitis is recognized at three main sites: the distal aspect of the third metacarpal or metatarsal bone, the distal aspect of the radius, and, less frequently, the distal aspect of the tibia. During lameness investigations, physitis has been noticed at other sites, such as the distal aspect of the femur and cervical vertebrae.

Physitis is seen in the fetlock region in foals aged 3 to 6 months and occurs at the distal aspect of the radius from 8 months to 2 years of age. Clinical signs are characterized by firm, warm, and painful enlargement of the growth plate, most commonly on its medial aspect. The proximal physis of the proximal phalanx also may be enlarged at

Fig. 57-2 • Physitis of the distal aspect of the right third metacarpal bone (growth plate), with some involvement of the proximal physis of the proximal phalanx, giving the fetlock an hourglass shape.

the fetlock, giving the fetlocks an hourglass shape when viewed from the dorsal aspect (Figure 57-2). Early signs at the distal radial or tibial growth plates include a convex appearance in the medial contour of the metaphysis just proximal to the physis; this should be a straight or slightly concave outline. Swelling also is located around the distal dorsomedial aspect of the radius (Figure 57-3). This dorsal component can lead the clinician to suspect that the condition has arisen from external trauma. As with the fetlock joint, warmth on palpation is present, as is tenderness when pressure is applied across the growth plate while the leg is held partially flexed. Full and forced flexion of the fetlock, carpus, or tarsus also may be resented. Most affected horses have changes at the distal medial aspect of the radius, but a few with preexisting carpus valgus conformation may develop the condition laterally. Bilateral lameness may be seen as a stilted gait. The conformation may become more upright through the pastern, and fetlock varus deformity may develop because the horse walks on the outside of the hoof to alleviate pain from pressure on the medial physis. I suspect that foals and yearlings that develop a carpus varus conformation (start to go bandy) are likely to have a subclinical form of physitis that encourages them to bear more weight on the lateral aspect of the forelimbs. If physitis continues unchecked, growth ceases on the medial side, exacerbating the carpus varus deformity, and ultimately, premature closure of the growth plate fixes the abnormal conformation. This chain of events also occurs in horses that develop physitis in the distal lateral aspect of the radius, resulting in a permanent carpus valgus conformation.

Fig. 57-3 • Dorsal view of a left forelimb; lateral is to the right. Physitis of the left distal radial growth plate with characteristic dorsomedial swelling and concavity of the outline of the medial aspect of the distal metaphysis is shown.

TREATMENT

Treatment centers on stable rest. Nonsteroidal antiinflammatory drugs can be helpful, particularly in horses that are very lame or have inflamed and painful growth plates. I have no experience of using corticosteroids or anabolic steroids in horses with physitis. Although body condition and conformation can vary, it is important to assess the nutrition of affected foals and other horses. Reduction of body weight and particularly a reduction in energy content in the diet must be made. Starving these horses completely is unwise, and it is important that mineral intake includes the correct balance of calcium and phosphorus and adequate copper and zinc. The length of rest required varies with the severity of the physitis and ranges from 2 weeks to 2 months. Corrective hoof trimming must also be undertaken, especially if the horse has developed an angular limb deformity (see Chapter 58). For varus deformity the unworn medial hoof wall must be removed (inside is lowered), and if the angulation is severe, fitting a lateral hoof extension is necessary.

Surgery usually is unsuccessful in horses that develop severe varus limb deformity resulting from physitis. This experience, coupled with the disappointing results obtained when operating on yearlings with congenital angular deformities, has led me to stop recommending periosteal elevation or physal retardation techniques in these groups of affected horses.

The prognosis for racing or other extreme athletic activities is good, provided the condition was not so severe that the conformation is permanently affected. If carpus varus and bench-knee conformation is marked, then the animal is likely to develop lameness from splints, carpalitis, sesamoiditis, or suspensory branch desmitis when more serious training is undertaken.

Chapter 58

Angular Limb Deformities

José M. García-López and Eric J. Parente

■ DIAGNOSIS AND CONSERVATIVE MANAGEMENT

Angular limb deformities are considered lateral or medial deviations to the long axis of the limb in the dorsal (frontal) plane. A lateral deviation distal to the carpus, termed *carpus valgus*, is the most common. Tarsus valgus and fetlock varus (a medial deviation) are the next most common, respectively. The toed-in or toed-out appearance that often accompanies an angular deformity is a concurrent rotational deformity and should not be confused with the angular deformity. An outward (external) rotation is usually

observed concurrently with a valgus deformity, and an inward (internal) rotation is seen with a varus deformity. No confirmed breed or sex predilection is known, but subjectively there may be some genetic predisposition. For a foal to be born with a mild bilateral carpal valgus and toed-out appearance is considered normal by most clinicians, and as the foal grows and the chest widens, the limbs straighten progressively.

Angular limb deformities usually are congenital, but they can be developmental, and have numerous causes. An acquired angular deformity is defined as worsening or failure of correction of the normal slight carpus valgus conformation in a neonatal foal. The cause and the severity and progression of the deformity are vital pieces of information that should be acquired before a treatment plan is formulated. Treatment is predicated by these factors. Foals are like molding plastic. The conformation changes slowly with growth. Genetics, nutrition, amount of exercise or weight bearing, and veterinary interventions all influence the conformation of the adult horse. Some of these factors can be influenced as a young horse matures, and small adjustments often need to be made to the treatment plan

as the animal grows. The foal should always be evaluated with the amount of remaining growth in mind and not just its present status. Because the greatest impact on conformation is made during periods of rapid growth, early recognition and regular reevaluations are extremely important to achieve a positive outcome.

Growth rates are most rapid in the neonate and slow considerably within the first year. Most of the growth from the distal radial and tibial physes occurs within the first 6 months of age. Most of the growth from the distal aspect of the third metacarpal bone (McIII) and the third metatarsal bone (MtIII) occurs within the first 3 months of age. Minimal changes take place beyond these times. Radiology alone cannot be used to determine the end of bone growth, because a physis is radiologically apparent long after clinically relevant growth has abated. In a normal foal, carpus valgus should be corrected to within 5 to 7 degrees of normal by 4 months of age and should be almost straight by 8 to 10 months of age.

EXAMINATION OF THE FOAL

It is critical to determine the extent and cause of the deformity before developing a management plan. Foals should be examined while they are standing and walking and radiographically. Occasionally foals are assessed in lateral recumbency.

Deformities can be assessed subjectively by visual examination. The foal should stand as squarely as possible, with the foot directly below the proximal part of the limb. Deviations from this stance exacerbate any deformities that truly exist. Because most foals stand still only transiently, repositioning the foal several times to evaluate each limb independently is often necessary. This allows observation of how the foal stands most frequently in a relaxed position. The clinician stands directly in front of the dorsum of the long bones for evaluation of the forelimbs, not necessarily at the front of the toe. The orientation of the toe may be affected by a concurrent rotational deformity, which confounds interpretation. Hindlimbs should be evaluated similarly but directly from behind. The forelimbs can also be evaluated by standing shoulder to shoulder with the foal, looking down the limb toward the ground.

All limbs also should be evaluated with the foal walking away from and toward the clinician. Breakover is determined for each foot, which may be helpful in deciding the most appropriate way to manage the foal. The entire assessment of a foal should be graded and recorded on video or on paper for future reference.

Radiology provides an objective assessment of angular deformity, but sequential radiographic examinations may be unreliable if the obliquity varies. Differences in radiographic projection can result in a misinterpretation of worsening or improvement, which is particularly true when trying to quantify small differences in the angle. Long, narrow (18 × 43 cm) cassettes should be used to measure the angle of the deformity, by evaluating the intersection of a line representing the long axis of the proximal and distal aspects of the long bones from the joint in question. This is more accurate in the carpus and fetlock than in the tarsus. Radiology is essential to identify cuboidal injury or malformation. Such a deformity dramatically worsens the

foal's prognosis. Foals with angular deformity resulting from cuboidal bone abnormalities usually have compromised range of motion, but this often is detected best with the foal in lateral recumbency.

PERIARTICULAR LAXITY

Periarticular laxity is the major cause of congenital angular limb deformities and often improves dramatically within the first 4 weeks of life, without any intervention, as the periarticular tissues become less elastic. The improvement is most dramatic in a windswept foal, which has a tarsus valgus of one limb and a concurrent varus of the other. Limited exercise is all that is required for these foals to become normal.

Infrequently the deformity can be so severe, particularly in the fetlock, that the foal is unable to bear weight on the sole of its foot. Immediate treatment is required to establish normal weight bearing. Custom-made glue-on shoes are particularly useful to prevent abnormal breakover and to keep the foot flat on the ground. If the foal has excessive laxity of the lateral collateral ligaments and a tendency to break over on the lateral side of the foot, a lateral extension shoe is used to maintain appropriate alignment of the limb. The foal should initially be restricted to a stall before turnout in a small paddock or round pen with just the mare. Soft tissues become progressively stronger, and normal activity can be permitted within a relatively short time. Allowing premature excessive exercise can lead to proximal sesamoid bone fractures (see Chapter 36) and other injuries. Glue-on shoes are usually required for several weeks, but they then should be removed to prevent contracture of the foot. External coaptation also should be avoided if possible. Splints are used only to maintain joint alignment if absolutely necessary. Splints are contraindicated to try to pull or push a limb straight. Rigid support from a splint or cast usually leads to greater soft tissue laxity. Trying to support a limb results in continued laxity and soft tissue wounds from bandaging. Every foal must be managed on an individual basis with the goal of achieving normal weight bearing and function while providing the minimal amount of support necessary.

ASYMMETRICAL PHYSEAL GROWTH

Asymmetrical growth of a distal physis is a cause of angular limb deformity. Greater growth from the distal physis of the radius medially compared with growth laterally results in carpus valgus. Continued asymmetrical growth precludes the normal correction anticipated with resolution of periarticular laxity. Greater growth from the lateral aspect of the distal physes of the McIII or the MtIII results in fetlock varus. With time and limited exercise (stall or small paddock turnout, alone with the mare) substantial self-correction occurs for most foals with angular deformities. Radiology can be used to evaluate objectively the degree of deformity and the difference in physal growth, but it is not always required.

Fetlock varus is often overlooked and affects the left hind fetlock most commonly, possibly because of in utero positioning. Because growth at the distal physis of the McIII and the MtIII terminates within a few months, early recognition of this deformity is critical.

TRAUMA-RELATED DEFORMITIES

Developmental causes of angular deformities are likely secondary to excessive or asymmetrical weight bearing and can be more serious than congenital abnormalities. Incomplete ossification of the cuboidal bones in a foal can result in cuboidal bone crush and a secondary angular limb deformity. The lateral carpal bones most commonly are affected, resulting in carpus valgus. Although the deformity is clearly apparent, the health and function of the joint is most critical. The carpi and tarsi of any premature or dysmature foal should be examined radiologically. Because ossification is incomplete, abnormal cuboidal bones appear round or in other shapes, and if crushing exists, the bones are wedge shaped, overlap opposing bones, or are fractured. If the foal's activity can be managed strictly in a hospital situation, no further support is recommended. Limited, strictly controlled exercise encourages appropriate ossification. If the foal's activity cannot be strictly managed and the foal has moderate strength, sleeve casts are recommended to prevent cuboidal bone crush. Sleeve casts should be changed or removed in 10 to 14 days in a growing foal. Radiological reevaluation every 2 weeks helps determine the length of time a cast is required.

Foals can also develop angular limb deformities secondary to lameness in the contralateral limb. If foals become non-weight bearing on a single limb, they adopt a tripod-like stance by bringing the contralateral limb more medial and toeing in. Over several weeks this results in asymmetrical bony growth of the nonlame limb and varus deformity of all joints, with internal rotation of the distal aspect of the limb. A dorsolateral toe extension can be placed on the foot of the nonlame limb to try to encourage a more abducted stance, but resolution of the primary lameness is the best way to prevent the contralateral limb deformity from occurring. Once the deformity has occurred, correction is improbable.

CONSERVATIVE MANAGEMENT

In most situations, judicious minimal intervention is all that is required to correct angular limb deformities. This includes limited small paddock exercise and careful attention to the foot. Trimming the foot and using shoe extensions can influence a foal's ability to self-correct an angular limb deformity by affecting the weight bearing and tracking of the limb. A foal younger than 4 months of age with mild carpus valgus likely requires no specific intervention. A foal with a moderate carpus valgus, toed-out appearance would benefit from shoes with dorsomedial extensions. This encourages the foal to adduct the limb and turn in more when breaking over. The result is more physiologically normal strain on the limbs, which should result in a straighter limb. A similar external appearance can be achieved by overtrimming the lateral hoof wall, but the effect is not the same. Although trimming the foot in this manner may give the appearance of an immediate benefit, it may have a negative long-term effect of an unbalanced foot, compensating for a limb with a deformity. This method has, however, been used for years with apparent success.

More aggressive intervention is infrequently required. Surgical intervention should be reserved for those foals

that are not improving fast enough for the amount of growth potential remaining. Therefore frequent reevaluation to monitor progress of a foal with an angular limb deformity is critical. Surgical intervention has a greater effect on a young foal because of the more rapid growth; thus early surgical intervention should be considered for a foal with a severe deformity.

■ SURGICAL MANAGEMENT

José M. García-López

A high proportion of foals with angular limb deformities are treated successfully conservatively, but surgical intervention is warranted if a deviation is severe or if deformity persists despite adequate management, including restriction of exercise and corrective farriery. Various surgical techniques aimed at accelerating or decreasing the growth on a particular side of the growth plate have been described.¹⁻⁷ Surgical technique depends on the age of the foal, the degree of angular limb deformity, the anatomical site, and whether the deformity is varus or valgus (Figure 58-1).

Before surgery, all the limbs should be assessed from the front, from the back, and while standing next to the limbs. Good-quality radiographs, which include a substantial length of the bones proximal and distal to the deviation, should be obtained to assess bone structure (Figure 58-2) and to determine the pivot point and pivot point angle of the deviation. The pivot point is the intersection of two lines drawn parallel to the long axis of the bones proximal and distal to the articulation in question (Figure 58-3). The pivot point indicates the origin of the deviation

and helps to determine whether the cuboidal bones, in the case of the carpus and tarsus, are involved in the deviation, or if deviation is caused by disproportionate physal growth only. Abnormalities in the structure of these bones can have a substantial influence on the effect of the procedure and the future athletic potential of the horse. The pivot point angle is the angle formed by the intersection of these two lines and indicates the severity of the condition.⁸

Hemicircumferential periosteal transection and elevation, or periosteal stripping, aims to accelerate growth on the concave side of the limb, laterally for valgus and medially for varus deformities.¹ Previous work on chicken radii had shown that a circumferential division of the periosteum, rather than a longitudinal one, resulted in increased bone growth. The proposal was that the periosteum functioned as a fibroelastic tube that spanned the diaphysis, provided an even tension between both epiphyses, and was responsible for the regulation of growth.^{1,9} A horizontal or circumferential division of the periosteum would result in a release of tension at the level of the growth plate, resulting in the induction of new bone production on the side of the division.

The procedure has been thoroughly described.⁴⁻⁶ Hemicircumferential periosteal transection and elevation is performed with the foal in lateral recumbency under general anesthesia, with the concave side of the affected limb uppermost. If the procedure is going to be performed bilaterally, dorsal recumbency is recommended. The position of the physis is identified using a 20-gauge needle. For a carpus valgus deformity, a 4- to 6-cm longitudinal incision is made between the common and lateral digital extensor tendons starting just proximal to the medial

Fig. 58-3 • Dorsopalmar radiographic image of a carpus with valgus deformity. Lateral is to the right. Lines are drawn parallel to the long axis of the radius (A) and third metacarpal bone (B). The point at which these lines intersect is known as the pivot point (PP), and the angle between them is the pivot point angle (PPA).

physis. The incision is extended through to the periosteum. Using a curved scalpel blade (No. 12), a horizontal incision is made 1 to 2 cm proximal and parallel to the physis, at the distal end of the initial incision (parallel to the skin incision), forming an inverted T. The periosteal flaps are elevated with the aid of a periosteal elevator and then allowed to return to the normal position. It is important to transect the remnant of the ulna, or if the ulna is ossified, it should be removed with the aid of rongeurs. In foals with hindlimb tarsus valgus the veterinarian should bear in mind that a fibular remnant may be present. The incision is closed routinely and the area is bandaged for 10 to 14 days. The foal is kept in a large stall or small paddock until the deformity has been corrected.

Hemicircumferential periosteal transection and elevation has been reported to exert its effects for up to 2 months, but the procedure can be repeated if further correction is needed.⁴ There are no reports of overcorrection of the deformity, although one of the Editors (MWR) is aware of a few foals in which transphyseal bridging techniques on the opposite of the limb were necessary after hemicircumferential periosteal transection, giving the distinct appearance that overcorrection occurred. Early reports suggested an approximately 80% success rate^{1,3}; however, more recent work indicates less favorable results.¹⁰⁻¹² A large retrospective study in Thoroughbred racehorses investigated racing performance after hemicircumferential periosteal transection and elevation.¹⁰ A lower percentage of

treated horses were able to start a race and had a lower starts percentile ranking number compared with half-siblings. Most of the foals appeared to respond favorably to hemicircumferential periosteal transection and elevation based on external appearance of the limbs, but preexisting conditions, such as abnormal cuboidal bone formation from incomplete ossification or osteoarthritis secondary to abnormal loading of the limb before correction, may have influenced subsequent performance.

The technique of physal stimulation, a modification of hemicircumferential transection and elevation, was reported to be successful.¹³ Briefly, a needle is inserted into the physis on the concave portion of the limb (for example, the distal lateral aspect of the radial physes for foals with carpus valgus limb deformity) and numerous needle punctures are made into the physis, but deep to the periosteum, in a fan-shaped fashion.¹³ I have no experience with this technique.

Angular limb deformities are probably the most common orthopedic problem affecting Thoroughbred foals.^{10,14} Early surgical intervention was previously recommended to take maximum advantage of the growth potential of the physis, to try to provide foals with excellent conformation, and to enhance sale value and possibly potential performance. Based on current knowledge, it now seems likely that a large number of foals with mild angular limb deformities underwent unnecessary surgery. The reported success for correction of angular limb deformities, particularly in the carpus, after hemicircumferential periosteal transection and elevation has been recently challenged. Foals with carpus valgus that underwent hemicircumferential periosteal transection and elevation were no more likely to improve than were those managed with stall rest and corrective farriery.^{11,12} Although the efficacy or need to perform hemicircumferential periosteal transection and elevation when treating foals with mild to moderate carpus valgus deviations is a matter of current debate, the same cannot be said necessarily for other regions of the limb, such as the tarsus and fetlocks, without further investigation.

Transphysal bridging is performed on the convex side of a deformity to decrease the growth rate on that side of the physis. Traditionally, transphysal bridging has been performed in young foals with severe deformities or in foals in which most of the growth in a particular physis has subsided. Transphysal bridging has been performed successfully using cortical screws with cerclage wire in a figure eight, with a small dynamic compression plate, or with orthopedic staples.^{4,6}

The foal is positioned in lateral recumbency under general anesthesia, with the convex side of the affected limb uppermost, or in dorsal recumbency. The position of the physis is identified and checked radiologically using a 20-gauge needle inserted into the physis. Stab incisions are made for placement of cortical screws and cerclage wire; one incision is made in the center of the epiphysis and the other approximately 2 cm proximal to the physis. Once the subcutaneous tissues between both incisions have been bluntly dissected, a 4.5- or 3.5-mm cortex screw is placed through each incision, slightly angled toward the physis. Screw size depends on the size of the foal, but 4.5-mm screws are preferred. Before complete tightening of the screws, a loop of 18-gauge wire is fed through the

proximal incision and positioned around the distal screw head. The wire is then tightened over the proximal screw head, forming a figure eight. Once the wire has been tightened, the screws are tightened and the incisions are closed routinely. When performing this procedure in the distal aspect of the tibia, the clinician should be aware of the contour of the tarsocrural joint, because placing the epiphyseal screw into the joint is possible. The screw should be angled more sharply toward the physis than in the distal aspect of the radius. Postoperatively the foal should be kept in a large stall and monitored closely. Follow-up radiographs are strongly recommended to assess the amount of correction. Prompt removal of the implants is essential, because overcorrection of the deformity is possible.

A surgical alternative to transphysal bridging has been described and is currently known as the transphysal screw technique.^{4,7} A single screw, either 3.5 mm or 4.5 mm in diameter, is inserted in neutral fashion across the growth plate through a small stab incision in order to create the desired compression on the convex side of the deformity, as with transphysal bridging (Figure 58-4). This technique has been successful in achieving adequate correction of angular limb deformities, with the advantage of a better cosmetic result. Postoperative care for horses treated with a transphysal screw is similar to that for transphysal bridging. Prompt removal of the screw just before correction is achieved is encouraged because overcorrection is possible and there is a lag phase between screw removal and continued growth on the operated side.

In foals and young horses with an angular limb deformity that persists after physal closure, corrective osteotomy or osteotomy can be performed. A step osteotomy (sagittal plane) or step osteotomy (dorsal plane) is preferred

Fig. 58-4 • Dorsoplantar radiographic image of a tarsus with valgus deformity after a transphysal screw procedure.

to a closing wedge ostectomy, because limb length is preserved and interfragmentary compression between the bone pieces is better.⁴ These techniques are generally considered to be salvage procedures.

Tarsus valgus deformities frequently go unrecognized by both owners and veterinarians, possibly from lack of observation of the foal from behind and the inherent offset position of the tarsus.^{15,16} Early recognition and sometimes more aggressive surgical management of tarsal angular limb deformities are critical to achieve satisfactory results. Although the distal tibial physis has a tremendous growth rate until 4 months of age, foals younger than 2 months of age responded more favorably to hemicircumferential periosteal transection and elevation than older foals. Transphyseal bridging was more effective than hemicircumferential periosteal transection and elevation, especially in foals older than 2 months of age.¹⁵ This is a substantial change from the previous perception that hemicircumferential periosteal transection and elevation alone were adequate when managing most tarsus valgus deformities in foals 4 to 6 months of age. Early recognition of incomplete ossification of the tarsal bones (Figure 58-5) is crucial, because the condition, if unrecognized, leads to collapse of the third or central tarsal bones, resulting in osteoarthritis.^{15,16} Of 22 foals with incomplete ossification of the tarsal bones, 73% had tarsus valgus deformities. Only 32% of the foals were able to achieve the intended use.¹⁶

Chapter 59

Flexural Limb Deformities in Foals

Robert J. Hunt

Flexural limb deformity is the inability to extend a limb fully. Generally hyperflexion of a region results from a disparity in the length of the musculotendinous unit relative to the length of the bone. The deformities are categorized as congenital or acquired and may occur during in utero development or at any time after birth. Different anatomical structures may be involved, including the digital flexor tendons, suspensory apparatus, joint capsule, and surrounding fascia, skin, and bone.¹⁻⁶

CONGENITAL FLEXURAL DEFORMITIES

Congenital deformities are present at birth, and the cause is often unknown. Although uterine malposition of the fetus is often discussed, because of the voluminous nature of the uterus and the ability of the foal to move, uterine malposition is an improbable cause of flexural deformity in most instances. Other documented causes include

exposure of the mare to influenza and ingestion of Sudan grass, locoweed, or other teratogenic agents during development of the fetus.^{2,3,7} Equine goiter, neuromuscular disorders, and defects in elastin formation or collagen cross-linking may be involved in the pathogenesis.

Congenital flexural deformities most commonly involve the distal interphalangeal (DIP) joints, carpus, tarsus, and metacarpophalangeal and metatarsophalangeal joints, singularly or in combination.² Both forelimbs are usually involved, and occasionally other variations of skeletal deformities are evident, such as hindlimb deformity (windswept), spinal deformity, rye nose, and cleft palate. Sporadically occurring deformities involving the scapulo-humeral, cubital, coxofemoral, or femorotibial joints may occur in combination with other congenital skeletal anomalies. Congenital flexural deformities are a common cause of dystocia in the broodmare, resulting in loss of the foal and subsequent reproductive loss of the mare.

Treatment for congenital flexural deformities varies with the anatomical location involved and severity of the condition. Therapeutic intervention for foals with severe flexural deformities associated with arthrogryposis or gross spinal deformities should be discouraged, and humane destruction is recommended. Surgical transection of the digital flexor tendons and palmar carpal fascia generally fails to alleviate this deformity. Splinting and casting is also futile, although rarely a foal has survived with limited athletic potential.

Mild flexural deformities of the carpal, metacarpophalangeal or metatarsophalangeal, or DIP joints resolve

Fig. 59-1 • Mild bilateral flexural deformity of the carpus. This degree of deformity is self-limiting.

spontaneously if the foal has the ability to stand, nurse, and ambulate on its own. Most foals with mild and moderate deformities of these sites respond favorably to physiotherapy, by manually extending the limbs every 4 to 6 hours for 15-minute sessions, or forcing the foal to ambulate (Figure 59-1). Heavy bandaging, splinting or casting, and the administration of oxytetracycline can be helpful.^{2,8} Foals with deformities advanced enough to require assistance to stand respond more rapidly after application of a cast, which should be changed every 2 to 3 days (Figure 59-2). If a carpal deformity severe enough to prevent standing is recognized at parturition, the foal should be heavily sedated, within 30 to 45 minutes, and full-leg casts should be applied with the limbs placed in extension. These should be changed within 24 hours and reset. Generally a rapid response is seen after the first or second application of casts. If the foal develops any complications with the casts or becomes distressed, casts should be removed. Commercially available articulating braces (Almanza Corrective Boot, www.redboot.com.ar/home.html; Equine Bracing Solutions, Trumansburg, New York, United States; Dynasplint Systems, Serverna Park, Maryland, United States) are available and allow adjusting the degree of extension in a specific region of the limb (Figure 59-3). As with all splints, caution must be exercised to prevent pressure sores. It is important to assist the foal in nursing and

Fig. 59-2 • Moderate unilateral flexural deformity of the right carpus.

Fig. 59-3 • Articulating brace used in foals with flexural deformity of the carpus.

to provide supportive care in an intensive neonatal facility, because these horses are at high risk for developing complications with other body systems.

Oxytetracycline (2 to 4 g) administered slowly intravenously is also beneficial, but it should not be used in a neonate until serum creatinine is within normal limits.⁸ Oxytetracycline may be given daily or every other day for three or four treatments. Complications of oxytetracycline administration include renal failure, diarrhea, and, most commonly, excessive laxity of other, normal joints. The precise mechanism of action for tendon relaxation remains speculative.

Flexural deformity of the DIP joint is most often self-limiting if the foal can stand without buckling forward.

Bandaging of the lower limb, physical therapy, and administration of oxytetracycline hastens recovery. If the foot angle is beyond 90 degrees (i.e., the dorsal aspect of the foot is in front of the vertical), casting or splinting may be necessary. Toe extensions are generally counterproductive and hinder ambulation of the foal.

Splints may be constructed from polyvinyl chloride (PVC) material, fashioned from fiberglass cast material, or purchased commercially. When splints are used for management of flexural deformity, the clinician must exercise extreme caution to prevent rub sores or pressure sores. Splints should be applied only for brief periods, in a schedule such as 4 to 6 hours on followed by 4 to 6 hours off. Properly applied casts are more effective, require less maintenance, and result in fewer pressure sores than splints.

Prognosis for future athletic performance is good for foals with congenital flexural deformities that respond favorably in the first 2 weeks of life. In general, if the foal is able to stand, nurse, and ambulate without assistance, most congenital flexural deformities are self-limiting and warrant a good prognosis. Foals may require several months to stop buckling dorsally at the carpus. Foals with flexural deformity of the metacarpophalangeal or metatarsophalangeal joints typically respond within the first or second week of life. Prognosis for future performance is poor for foals with severe flexural deformity of the carpus, tarsus, or metacarpophalangeal or metatarsophalangeal joints that show no improvement after several days of treatment and have difficulty ambulating without assistance after 1 to 2 weeks of treatment. Foals with congenital flexural deformities involving the scapulohumeral, cubital, coxofemoral, or femorotibial joints have a poor prognosis for future athletic performance.

ACQUIRED FLEXURAL DEFORMITIES

Acquired flexural deformities develop after birth until the second year of life. Commonly involved areas include the DIP joint, metacarpophalangeal joint, and carpus. Acquired flexural deformity of the DIP joint is recognized at 3 to 6 months of age, carpal flexural deformity is seen at 1 to 6 months of age, and flexural deformity of the metacarpophalangeal joint is recognized later, during the yearling or early 2-year-old year (9 to 18 months).⁹

Common causes of flexural deformity of the metacarpophalangeal joint and carpus are believed to include a genetic propensity for rapid growth, overnutrition, and pain. Relative excess feeding or overassimilation of nutrients in foals that have an inherent potential for rapid physical development is a frequent finding in foals with acquired flexural deformity, especially involving the carpus and the metacarpophalangeal joint. During periods of rapid bone lengthening the potential for passive elongation of the tendinous unit is limited because of the accessory ligaments, and a discrepancy in the length of the bone-to-tendon unit may result. Another theory is that a pain-mediated response during physeal dysplasia results in altered load bearing on the limbs. This is believed to initiate secondary contraction and shortening of the musculo-tendinous unit, resulting in limited extension of a region. Any cause of pain resulting in prolonged reduced weight bearing in a limb may result in this syndrome.

Genetics may be involved with the development of acquired flexural deformity of the DIP joints (club feet). Other factors include diet and exercise. Protracted lameness from another cause such as osteochondrosis of the upper limb also predisposes to development of acquired DIP joint deformity. It is therefore important to identify an associated source of lameness.

Early clinical signs of acquired flexural deformity of the DIP joint consist of a prominent bulge at the coronary band, increase in length of the heel relative to the toe, and failure of the heel to contact the ground after trimming (Figure 59-4, A). Eventually the foot develops a boxy shape with a dish shape along the dorsal hoof wall. This deformity is commonly accompanied by a back-at-the-knee (calf-knee) conformation (see Figure 59-4, B).

Treatment for foals with acquired flexural deformity of the DIP joint initially entails exercise restriction, frequent lowering of the heel, dietary restrictions, and pain control with nonsteroidal antiinflammatory drugs such as flunixin meglumine. Weaning the foal may be advantageous. If the toe becomes excessively worn, constructing a cap over the toe with one of the commercially available hoof composites may aid in protecting the toe and dorsal aspect of the sole from bruising and may temporarily serve as a lever arm. Although elevating the heel with a wedge shoe or pad provides comfort for the foal, the deformity gradually worsens, and eventually obtaining a normal angle and shape to the hoof is difficult. Glue-on shoes should likewise be used with caution, because they tend to promote a box shape to the foot. Oxytetracycline may be used but exacerbates the back-at-the-knee conformation.

If no improvement is achieved within 1 to 2 months of conservative treatment, surgical intervention with desmotomy of the accessory ligament of the deep digital flexor tendon (ALDDFT) is recommended. When surgical treatment is combined with a trimming program, hoof conformation and function will be much improved. The owner should be made aware of the potential for a blemish at the surgical site. In a group of 23 Standardbreds treated for flexural deformity of the DIP joint, 11 foals had desmotomy of the ALDDFT, of which six raced or were sound. All foals operated on by 8 months of age had a favorable outcome. None of the 12 foals that did not undergo surgery had a favorable outcome.¹⁰

Foals in which the dorsal aspect of the hoof is in front of the vertical (hoof angle >90 degrees) are candidates for deep digital flexor tenotomy, although desmotomy of the ALDDFT has been helpful in some foals when combined with farriery, oxytetracycline, and phenylbutazone therapy. With deformities of this severity, contracture of the joint capsule and surrounding soft tissues often precludes successful management for an athletic future.

Early treatment of foals with flexural deformity involving the metacarpophalangeal and metatarsophalangeal joints consists of eliminating pain through the use of analgesics, exercise restriction, and correction of any underlying nutritional problems. Any extremes in hoof angle should be corrected, and the foot should be trimmed at an angle suitable for that individual. If no improvement is achieved with conservative treatment, desmotomy of the accessory ligament of the superficial digital flexor tendon or of the ALDDFT may be helpful in select instances of moderate deformity. If the underlying cause is not

Fig. 59-4 • **A**, Advanced flexural deformity of the right front distal interphalangeal joint. The heel does not contact the ground, and the dorsal aspect of the hoof wall is dish shaped. **B**, Calf-kneed conformation is associated with a clubfoot.

addressed, the benefits of surgery will be only transient. Foals with severe deformity resulting in the limb persistently buckling forward rarely respond favorably to conservative or surgical treatment. Transection of both accessory ligaments or of the superficial digital flexor tendon may

provide some improvement in horses with advanced deformity.

Treatment for acquired flexural deformity of the carpus is aimed at eliminating the underlying cause, and if the deformity is recognized early, conservative management is

generally effective. The nutritional program (see Chapter 55) and growth chart for the foal should be reviewed and errors corrected if found. The nutritional program is often already balanced in some of these foals, and treatment is empirical and focused on reducing the energy intake and slowing the growth. Dietary restriction, limitation of turnout schedule and exercise, and treatment with nonsteroidal antiinflammatory drugs are currently accepted practice. Feeding of grain and other sources high in energy and protein to the mare should be restricted in an attempt to reduce the nutritional quality of the milk and to prevent the foal from ingesting grain while eating with the mare. In foals with severe deformity, limiting access to milk through muzzling the foal and stripping the mare periodically throughout the day may be attempted. However, weaning the foal from the mare to control the diet is generally easier. Acquired carpal flexural deformities may require weeks to months to correct. Splints, bandaging, and oxytetracycline may provide some benefit. These benefits are often short-lived if the underlying cause is not addressed.

Rupture of the common or lateral digital extensor tendon is often mistaken for flexural deformity of the

metacarpophalangeal joint or carpus because the foal knuckles forward when walking. The disorder may be recognized shortly after birth or generally by 3 to 4 days of life; rarely it may occur in foals up to 3 weeks of age. Diagnosis is based on the characteristic gait of knuckling forward at the fetlock and the presence of a fluctuant swelling over the dorsolateral surface of the carpus (Figure 59-5). There is usually palpable laxity in the extensor tendons. The limb can be placed in a normal position when the foal is standing. There may be a greater tendency to rupture the extensor tendons in foals with flexural deformities, especially in those that are born prematurely.

Treatment consists of applying a heavily padded splint over the dorsal or palmar aspect of the lower limb to prevent knuckling forward and traumatizing the dorsum of the pastern and fetlock. Dorsally placed splints are most effective if they do not slip or rotate. Casting may be used but is generally not necessary. Stall confinement is important until the foal develops the ability to use the limb. Foals generally require 1 week to 2 months of splinting and bandaging before they learn to ambulate properly. The prognosis is invariably good.

Chapter 60

Cervical Stenotic Myelopathy

Richard J. Piercy*

Cervical stenotic myelopathy (CSM; wobbler syndrome), a common spinal cord disease of horses, is characterized by malformation of the cervical vertebrae, stenosis of the vertebral canal, and spinal cord compression.¹ The age of onset is typically 6 months to 3 years, although mature horses are also sometimes affected. Young horses with the disorder have commonly grown rapidly and are more likely to have developmental orthopedic disease of the appendicular skeleton than peers.² Male horses are more frequently affected than females.³ CSM has been reported in most light and draft horse breeds, although Thoroughbred and Warmblood horses appear to be particularly predisposed.

CLINICAL SIGNS

The clinical signs of spinal cord compression are usually insidious in onset, although owners sometimes report a traumatic incident before recognizing any ataxia. Such traumatic incidents may occur because of mild or previously unrecognized neurological deficits (e.g., occasional tripping) that result in a fall.

Horses with CSM generally have neurological deficits that are recognizable in all limbs, characterized by symmetrical weakness, ataxia, and spasticity.⁴ In most instances the hindlimbs are more severely affected than the forelimbs, probably because of the more superficial location of hindlimb tracts in the white matter of the spinal cord. At rest, severely affected horses may have a base-wide stance and delayed responses to proprioceptive positioning, whereas at the walk, weakness may be manifest by stumbling and toe dragging. Horses with prolonged clinical signs of CSM may therefore have hooves or shoes that are chipped, worn, or squared at the toe. Ataxia (a sign associated with defective proprioception) is evident as truncal sway at a walk, inconsistent and erratic foot placement, and circumduction and posting (pivoting on the inside limb) of the hindlimbs during circling. Moderately to severely affected horses sometimes have lacerations on the heel bulbs and medial aspects of the forelimbs from overreaching and interference. Spasticity, characterized by a stiff-legged gait and exaggerated movements, may be observed in moderately affected horses, especially in the forelimbs or in the hindlimbs when stepping over curbs or poles. When prompted to back, horses may stand base-wide, lean backward, and drag the forelimbs. Occasionally, signs associated with the forelimbs may be more severe than those in the hindlimbs, particularly in horses with caudal cervical lesions, probably because of involvement of local spinal cord grey matter.

A grading scale (0 to 5) is often used to score horses with signs of spinal ataxia and weakness: 0, normal; 1, very mild deficits detectable only with complex movements (e.g., walking with head elevated, on an incline or when circling); 2, mild-moderate deficits that are detectable at the walk; 3, marked deficits obvious at the walk; 4, severe deficits that result in difficulty remaining standing; 5, recumbent. Some clinicians favor an approach in which

*The author acknowledges and appreciates the work of Dr. Bonnie Rush, who authored this contribution in the previous edition.

Figure 60-1 • Lateral-lateral radiographic image of the caudal aspect of the neck of a 4-year-old Paint gelding with cervical pain and spinal ataxia. Cranial is to the left. Note the abnormal intercental articulation between the sixth and seventh cervical vertebrae (arrows). This represents end-stage diskospondylosis.

individual limbs are scored separately for signs of ataxia and weakness, with a global score being used to summarize the total neurological deficit. Such an approach is helpful when evaluating disease progression and response to treatments.⁵

Asymmetrical ataxia and paresis are observed occasionally in horses with dorsolateral compression of the spinal cord caused by proliferative, degenerative articular processes and periarticular soft tissues.⁶ Infrequently, signs of compressive radiculopathy, such as cervical pain, atrophy of the cervical musculature, cutaneous hypalgesia, and hyporeflexia of cervical reflexes adjacent to the site of spinal cord compression may be evident. These signs are more commonly observed in horses older than 4 years of age with moderate-to-severe arthropathy of the fifth to seventh cervical vertebrae (C5 to C7) and usually result from peripheral nerve compression by proliferative articular processes as the nerve root exits the vertebral canal through the intervertebral foramen.⁷

In some instances arthropathy of the caudal cervical vertebral articular processes may produce forelimb lameness, caused by spinal nerve root compression, without producing clinical signs of spinal cord compression.⁸ Affected horses typically have a short cranial phase of the stride and a low forelimb foot arc and may stand or walk with the head and neck extended (see Chapter 53). Rarely, diskospondylosis of the cervical vertebrae produces a short-strided gait and cervical pain, with or without spinal ataxia (Figure 60-1). Horses with diskospondylosis or arthropathy of the caudal vertebrae may exhibit signs of lameness, pain, or stiffness with the neck in only certain positions or when the head and neck are manipulated or the horse is turned. For example, some affected horses may be unwilling to turn the neck laterally when offered food.

Dynamic spinal cord compression usually occurs in younger horses (<2 years of age) and is associated with instability of the cervical vertebrae, particularly between C3 and C6. Dorsal laminar extension, caudal epiphyseal flare, or abnormal ossification patterns may contribute to the problem. Static vertebral canal stenosis (type II) is characterized by constant spinal cord compression, regardless

Figure 60-2 • Lateral-lateral radiographic image during myelographic examination of the fifth to seventh (C7) cervical vertebrae of a 3-year-old Thoroughbred colt with static spinal cord compression. The dorsal and ventral contrast columns are attenuated by more than 50% at the fifth and sixth (C6) and sixth and seventh cervical vertebral articulations.

of neck position (Figure 60-2), and is seen usually in older horses.⁹ It generally results from osteoarthritis (OA) of the articular processes and proliferation of periarticular soft tissue structures. Synovial cysts, which are often associated with OA of the articular processes, may produce waxing and waning, or acute-onset asymmetrical neurological signs. In some horses with static compression, flexion of the neck stretches the ligamentum flavum and relieves spinal cord compression, whereas extension exacerbates the problem.

DIAGNOSIS

The following neurological disorders should be considered potential differential diagnoses and may produce signs similar to or indistinguishable from CSM: equine protozoal myeloencephalitis (EPM), equine degenerative myeloencephalopathy (EDM), equine herpesvirus-1 (EHV-1) myelitis, occipitoatlantoaxial malformation, spinal cord trauma, vertebral fracture, vertebral abscess or neoplasia, and verminous myelitis (see Chapter 11).

Horses with traumatic cervical vertebral disorders usually exhibit pain during manipulation or palpation of the neck, and the disorder may sometimes be differentiated from CSM by standing radiographic examination. Occipitoatlantoaxial malformation (see Chapter 53) occurs primarily in Arabian horses and is diagnosed definitively by radiological evaluation (see Figure 53-4, B). EDM is diagnosed by exclusion (unremarkable cerebrospinal fluid [CSF] cytological examination findings, negative immunoblot analysis for *Sarcocystis neurona*, and negative radiological findings and myelographic examination findings). A veterinarian may suspect EDM based on the age (usually less than 18 months) and during neurological examination (hyporeflexia, and similar degrees of ataxia in the forelimbs and hindlimbs), but definitive diagnosis is achieved only by postmortem examination. Although several breeds have been reported with the disease, EDM appears to have a familial predisposition in Standardbred horses.¹⁰ Horses with EHV-1 myelitis may have urinary incontinence, poor tail tone, and hindlimb lower motor neuron weakness. Signs associated with cranial nerve involvement may occasionally be observed. In EHV-1 myelitis, CSF evaluation

typically reveals xanthochromia and albuminocytological dissociation (high protein concentration, normal cell count); a rising EHV-1 serum antibody titer, virus isolation, and polymerase chain reaction (PCR) diagnosis all may be used to provide supportive evidence of EHV-1 myelitis. In areas where EPM is endemic (such as North and South America) or in horses exported from these regions, distinguishing between EPM and CSM can be difficult. Asymmetrical ataxia, focal sweating, and focal muscle atrophy should direct diagnostic efforts toward EPM; however, symmetrical spinal ataxia does not preclude a diagnosis of EPM. EPM-affected horses with symmetrical ataxia are differentiated from those with CSM on the basis of standing radiographic examination, CSF immunoblot analysis for *S. neurona*, and, in some circumstances, myelographic evaluation (see comments on equine myelography, later). Immunoblot analysis of CSF is frequently positive, however, if horses affected by CSM are in a geographical area with a high seroprevalence of EPM. Therefore differentiation of these two conditions should not be determined on the basis of CSF analysis alone. Findings of cytological analysis of CSF are usually unremarkable in horses with CSM, although mild xanthochromia or slightly increased protein concentration may be observed in affected horses, especially if signs have developed acutely, perhaps precipitated by trauma.

Plain radiography of the cervical vertebrae can be used to assess the likelihood of CSM in horses with spinal ataxia.¹¹ Accurate assessment of cervical radiographs requires a precise lateral-lateral radiographic image of the cervical vertebrae,¹² ensuring that the ventral prominences of the transverse processes are perfectly overlying each other. Radiographic obliquity results in indistinct margins of the ventral aspect of the vertebral canal, and in erroneous values for objective measurements. Obtaining precise lateral-lateral radiographs of the cervical vertebrae in recumbent horses is difficult, so whenever possible, plain or digital radiographs should be obtained in the standing, sedated horse.

Cervical radiographs should be evaluated subjectively and objectively. Subjective interpretation is based on examining for the presence of five characteristic malformations of the cervical vertebrae, which include (1) flare of the caudal epiphysis of the vertebral body (the so-called “ski-jump appearance”); (2) abnormal ossification of the articular processes; (3) subluxation or malalignment between adjacent vertebrae; (4) extension of the vertebral caudal dorsal lamina; and (5) OA of the articular processes (Figure 60-3). Estimating the importance of lesions identified through subjective interpretation can be difficult and is based on the clinician’s experience and interpreting the balance of probability. For example, OA of (especially the caudal) vertebral articular processes is recognized commonly in normal horses.¹³ Hence recognition of characteristic vertebral malformations is considered supportive in diagnosis at best.¹⁴

Objective assessment of vertebral canal diameter is more accurate than subjective evaluation of vertebral malformation for identifying young horses affected by CSM, but may lead to false negative diagnoses in older horses.⁹ Both intervertebral and intravertebral measurements are used. The sensitivity and specificity of the intravertebral sagittal ratio for identifying horses affected by CSM are approximately 90% for vertebral sites between the fourth

Figure 60-3 • Lateral-lateral radiographic image of the midneck region of an 8-month-old Quarter Horse colt with spinal ataxia caused by cervical stenotic myelopathy. Bony malformations consistent with cervical stenotic myelopathy include flare of the caudal epiphyses (curved arrows), caudal extension of the third cervical vertebra dorsal lamina (arrows), and malalignment of the articulation of the third (C3) and fourth (C4) cervical vertebrae.

Figure 60-4 • Lateral-lateral radiographic image of the third (C3), fourth (C4), and fifth (C5) cervical vertebrae of a 2-year-old Thoroughbred colt with cervical stenotic myelopathy. The sagittal ratio is determined by dividing the intravertebral minimum sagittal diameter (double curved arrow) by the width of the vertebral body (line). The intervertebral minimum sagittal diameter is measured from the caudoventral aspect of the dorsal lamina of C3 to the craniodorsal aspect of the vertebral body of C4 (double arrow below the smaller arrows). There is caudal extension of the dorsal lamina of C3 (smaller arrows), and there is malalignment at the articulation of C3 and C4.

and seventh cervical vertebrae, suggesting that generalized stenosis of the vertebral canal may be the most important factor in the development of CSM (especially in young horses).¹¹ The intravertebral sagittal ratio is calculated by dividing the minimum sagittal diameter of the vertebral canal (the narrowest perpendicular distance from the dorsal aspect of the vertebral body to the ventral border of the dorsal lamina) by the maximum width of the cranial vertebral physis (from the vertebral canal) (Figure 60-4). Because the vertebral body is located within the same anatomical plane as the vertebral canal, this ratio negates effects of magnification resulting from variability in object-plate distance. In most normal horses, the sagittal ratio exceeds 52% from the fourth to sixth cervical vertebrae and

56% at the seventh cervical vertebrae in horses greater than 320 kg. The positive predictive value of such measurements is probably higher, and the negative predictive value lower, in ataxic horses from countries where conflicting diagnoses (such as EPM) are not routinely encountered (i.e., false-positive results are less likely, but false-negative results are more likely because the underlying prevalence of CSM in ataxic horses is higher). Similarly, the positive and negative predictive values of objective cervical radiography measurements in the absence of ataxia (e.g., during prepurchase radiography) have not been evaluated, but false-positive results are likely to be more common and false-negative results less common, because the prevalence of CSM in this population is much lower. Judicious use of additional diagnostic tests (e.g., CSF evaluation) to help rule out other differential diagnoses should be considered to increase pretest probability, especially in countries where other causes of spinal ataxia are common.

Some clinicians advocate use of ratiometric measurements that take into account the distance between adjacent vertebrae (intervertebral ratios) (see [Figure 60-4](#)) based on the rationale that most compressive lesions occur between, rather than within, the vertebrae.¹⁵ Particularly high-quality radiographs are usually required for such measurements, but analysis suggests that this approach may be helpful in differentiating CSM from other conditions.¹⁶ Further comparison of both methods in a large group of horses is needed based on a gold standard diagnosis established at postmortem examination, because myelography is problematic (see discussion later). However, available postmortem material may be skewed toward severely affected horses because these horses may more often be euthanized.

A semiquantitative scoring system developed by Mayhew and colleagues¹⁷ is advocated in foals younger than 1 year of age for assessment of cervical radiographs for diagnosis of CSM. The scoring system combines objective measurement of vertebral canal diameter and subjective evaluation of vertebral malformation. Stenosis of the vertebral canal is assessed by determination of the intervertebral and intravertebral minimum sagittal diameter (see [Figure 60-4](#)). The intervertebral and intravertebral minimum sagittal diameters are corrected for radiographic magnification by dividing these values by the length of the vertebral body. The maximum score for cervical vertebral stenosis is 10 points. Cervical vertebral malformation is determined by subjective assessment of five categories: (1) encroachment of the caudal epiphysis of the vertebral body dorsally into the vertebral canal, (2) caudal extension of the dorsal lamina to the cranial physis of the adjacent vertebra, (3) angulation between adjacent vertebral bodies, (4) abnormal ossification of the physis, and (5) OA of the articular processes. The maximum score allotted for each category of bony malformation is 5 points. A total score of 12 or higher (maximum total score 35) confirms the radiological diagnosis of CSM. Stenosis of the vertebral canal and malalignment between adjacent vertebrae are the most discriminating parameters in this semiquantitative scoring system to differentiate normal from affected foals.

Radiology may be used to predict the likelihood of CSM, and in countries where conflicting differential diagnoses are rare (and in the absence of other signs to the contrary), radiology is often considered sufficient to make

a presumptive diagnosis of cervical compression without the need for further tests. In countries where EPM or other conflicting differential diagnoses are possibilities, many clinicians favor myelography for diagnosis. Unfortunately, for most intervertebral sites, myelography results in a high number of false-positive and false-negative results.¹⁸ Myelography remains, however, a prerequisite if surgical intervention is considered a viable option on the basis of severity of signs and the owner's wishes and expectations (see later). This is because standing radiography does not definitively pinpoint the actual site of the compressive lesion(s).¹¹ Typically during myelography, however, clinicians obtain additional radiographic images, such as the lateral-lateral projections in neutral, extended, and flexed positions, although the last technique in particular results in more false-positive diagnoses.¹⁸ Radiography of the neck in different positions does, however, enable the clinician to attempt to differentiate between static and dynamic compressive lesions. Note that neck flexion and extension while horses are under anesthesia are contraindicated if there is evidence of compression on the initial neutral views. Ventrodorsal images may be attempted in small or young horses, especially in the cranial aspect of the neck, and may demonstrate an asymmetrical compressive lesion that might otherwise account for some false-negative diagnoses in larger horses.

Various techniques have been used for interpreting equine myelograms. In normal horses there should be no or minimal change to the width of the dorsal dye column, but it is common to have loss of the ventral dye column. Consequently, most commonly at intervertebral sites between C2 and C6, diagnosis of spinal cord compression is made on the basis of a 50% or greater decrease in the sagittal width of the dorsal and ventral contrast columns in comparison with the column width at the immediate cranial or caudal midvertebral site.¹² At C6-C7, a reduction of more than 20% of the dural diameter measured in the midbody region is best used to diagnose compression, because this measurement has a relatively high sensitivity and specificity.¹⁸ Clinicians may favor use of different "cutoff" values for exclusion or inclusion of diagnosis based on the consequence of the derived decision (i.e., possible euthanasia or surgery).¹⁶ As in interpretation of plain radiographs, the positive predictive value for myelography is likely to be higher in ataxic horses from countries without many conflicting differential diagnoses because the prevalence of true vertebral compression in ataxic horses is relatively higher.

Horses should be monitored for 24 hours after the myelographic procedure for depression, fever, seizure, or more severe ataxia. Worsening of neurological status after myelography may result from spinal cord trauma during hyperflexion or as a result of the general anesthesia or recovery, iatrogenic puncture of the spinal cord, or chemical meningitis. Administration of phenylbutazone (4.4 mg/kg orally [PO] q24h) 1 day before until 1 day after myelographic examination is recommended.

Additional techniques that have been used or proposed for evaluating horses with compressive myelopathy include electromyography of the cervical musculature (examining for presence of signs of local muscle denervation caused by grey matter or peripheral nerve disease),¹⁹ transtentorial magnetic stimulation,²⁰ and kinematic gait analysis,²¹ but

Figure 60-5 • A, Ultrasonographic examination of the articulation of the fifth and sixth cervical vertebrae (coronal image). The cranial articular process of the sixth cervical vertebra (*arrows*) is superficial to the caudal articular process of the fifth cervical vertebra. **B**, Ultrasonographic examination during arthrocentesis of the articulation of the fifth and sixth cervical vertebrae (transverse image). A 15-cm spinal needle is entering the ventrolateral aspect of the joint (*white arrows*) deep to the cranial articular process of the sixth cervical vertebra (*black arrows*).

such techniques require further validation before their widespread use is recommended. Antemortem diagnosis of CSM therefore has inherent problems and limitations, of which the clinician should be aware, but a combination of tests and methodologies taken in the context of the signalment, history, and comprehensive physical and neurological examinations likely optimizes accurate diagnosis.

CONSERVATIVE MANAGEMENT

Successful conservative management of foals younger than 1 year of age with CSM has been achieved using the paced diet program.^{17,22} The goal of this dietary program is to retard bone growth, enhance bone metabolism, and allow the vertebral canal diameter to enlarge to relieve spinal cord compression. This dietary program is restricted in energy and protein (65% to 75% of National Research Council [NRC] recommendations) but maintains balanced vitamin and mineral intake (minimum 100% NRC recommendations). Vitamins A and E are provided at 3 times NRC recommendations, and selenium is supplemented to 0.3 ppm. Roughage is provided by pasture or low-quality (6% to 9% crude protein) timothy hay. Dietary regimens are individually formulated according to the age and weight of the foal. Solitary stall confinement is recommended to minimize repetitive spinal cord compression caused by dynamic instability.

Most clinicians advocate antiinflammatory therapy in all horses with CSM.⁹ Administration of glucocorticoids and/or nonsteroidal antiinflammatory drugs may reduce edema and provide transient improvement in neurological signs or may reduce compression from inflamed associated soft tissues. Some clinicians advocate use of dimethyl sulfoxide, particularly in horses in which clinical signs have developed acutely. Spontaneous recovery from CSM without dietary management or surgical intervention is not reported.

Horses with cervical pain and forelimb lameness caused by cervical vertebral arthropathy may benefit from intraarticular administration of corticosteroids or chondroprotective agents. Intraarticular administration of medication is performed with ultrasound guidance using a 15-cm

(6-inch), 18-gauge spinal needle in a standing, sedated, or recumbent horse.²³ The cranial articular process of the more caudal vertebra is superficial to the caudal process of the cranial vertebra (Figure 60-5, A). The articular space is accessed at the cranioventral opening of the articular facet, which is angled approximately 60 degrees from the ultrasound beam. The needle should be introduced 5 cm cranial to the joint and inserted at a 30-degree angle to the skin surface (Figure 60-5, B). Joint penetration should be confirmed by aspiration of synovial fluid. If the neck is extended, the transverse process of the cranial vertebra may obscure the path to the articulation. Intraarticular administration of triamcinolone acetonide (6 mg per joint) or methylprednisolone acetate (100 mg per joint) has produced a reduction in cervical pain in more than 50% of horses with arthrosis of the articular processes.²⁴ The goal of intraarticular antiinflammatory therapy should be to improve cervical mobility, reduce cervical pain, and eliminate forelimb lameness. In my experience, intraarticular therapy rarely improves spinal ataxia presumed to be associated with articular process OA.

SURGICAL TREATMENT

Surgical intervention is the most widely reported therapeutic approach for (particularly adult) horses with CSM. Cervical vertebral interbody fusion (ventral stabilization) was first described in 1979 for horses with dynamic spinal cord compression, and it is widely performed, particularly in certain centers.²⁵ The procedure fuses adjacent vertebrae in the extended position, which provides immediate relief of most dynamic spinal cord compressive lesions while preventing repetitive spinal cord trauma. Dorsal laminectomy (subtotal Funkquist type B) is described for horses with static CSM and provides immediate decompression of the spinal cord.²⁶ Portions of the dorsal lamina, ligamentum flavum, and joint capsule overlying the site of spinal cord compression are removed during dorsal laminectomy. This procedure effectively decompresses the spinal cord. However, it has been associated with substantial postoperative complications²⁷ and is not widely performed. Interbody fusion is an alternative to dorsal laminectomy for

horses with static compressive lesions because after cervical vertebral fusion the articular processes remodel and soft tissue structures atrophy, resulting in delayed decompression of the spinal cord over several months.²⁸

Cervical vertebral fusion improves the neurological status of 44% to 90% of horses with CSM, and 12% to 62% of horses return to athletic function.^{27,29} Of the horses that return to athletic function, approximately 60% are able to perform at the level of intended use, including racing, jumping, and pleasure performance activities. The anticipated magnitude of improvement is one to two neurological grades after cervical fusion. Occasionally, three grades of improvement in neurological status have been achieved. However, it is unusual for a horse with grade IV neurological deficits to become neurologically normal after cervical vertebral fusion. Rarely, a domino effect can occur in horses after vertebral fusion, wherein spinal cord compression develops at the intervertebral site adjacent to the site of fusion. This may result from added forces at the adjacent site or natural progression of the disease.³⁰ Subtotal laminectomy is reported to improve the neurological status of 40% to 75% of horses with static compression.²⁶

Fatal postoperative complications have been reported with surgical management of horses with static compressive lesions of the caudal cervical vertebrae (subtotal laminectomy and interbody fusion). Complications directly related to the surgical procedure include vertebral body fracture, spinal cord edema, and implant failure. Seroma formation is common after cervical vertebral interbody

fusion and can be minimized by use of a pressure bandage maintained over the surgical site for 2 to 3 weeks.²⁷

The most important horse-related factor for determining postoperative prognosis is duration of clinical signs before surgical intervention. Horses with neurological gait deficits present for less than 1 month before surgery are more likely to return to athletic function than are horses with signs of greater than 3 months' duration.²⁷ The number of spinal cord compressive sites and horse age do not appear to affect the long-term outcome of horses with cervical vertebral interbody fusion. Horses with dynamic compressive lesions appear to have a better postoperative result than those with static compressive lesions. Horses with lesions involving the sixth and seventh cervical vertebrae have a less favorable prognosis than those with lesions affecting the third to fifth cervical vertebrae.

The duration of convalescence and rehabilitation after cervical vertebral interbody fusion is approximately 12 to 18 months, and a horse's neurological status may continue to improve throughout that time. An individualized exercise program dependent on capability, projected use, and neurological status should be designed to promote muscular strength and coordination. Extended exercise at slow speed, including ponying (being led from another horse), working over poles, and lunging on inclines, is recommended during rehabilitation to build muscular strength. The point at which the horse is competent to return to athletic function after cervical vertebral interbody fusion should be determined by neurological examination.

Arthritis

Chapter 61

Osteoarthritis

John P. Caron

Joints are highly differentiated structures composed of a number of connective tissues including bone, articular cartilage, and periarticular soft tissues, all of which contribute to normal joint function and undergo changes in structure and metabolism in disease.^{1,2} From the point of view of joint diseases, perhaps the most important of these components is articular or hyaline cartilage, composed principally of a precisely organized arrangement of collagens and proteoglycans. This tissue is responsible for the load-distributing functions of the joint, and, in health, cartilaginous surfaces glide over one another in a virtually frictionless manner, even when under substantial load. In joint trauma or osteoarthritis (OA), the normal structure and function of articular cartilage are deranged, leading to biochemical, structural, and biomechanical abnormalities in all joint tissues. If the trauma is uncorrected, the result is progressive joint destruction, a process likened to organ failure in other body systems. Joint disease is a particularly prevalent cause of lameness and as such is an expensive equine health problem.³⁻⁵ An understanding of the biology and pathobiology of joints enables the clinician better to diagnose joint disease and to provide appropriate treatment and prevention recommendations.

STRUCTURE AND FUNCTION OF NORMAL JOINTS

Synovium and Synovial Fluid

The synovium is a vascular connective tissue lining the inner surface of the joint and consists of the cells of the synovial intima and a subsynovial stroma; the latter is composed of various amounts of fibrous, areolar, and fatty tissues. The synovium covers all articular surfaces, excluding articular cartilage and localized areas of bone. However, synovium is not uniform throughout the joint, and dense connective tissue may be found in its place in areas predisposed to trauma. Because the synovial lining bears neither true epithelium nor conventional basement membrane separating the joint cavity from the synovial vasculature, no true synovial membrane exists. Rather the intima and

subsynovial tissues comprise a structural and functional continuum that acts as a macromolecular sieve.

The synovial intima is lined by a diverse population of synoviocytes, which have been classified according to their ultrastructure and with the use of specific antisera.⁶⁻⁸ The three cell types are type A cells, of macrophage origin; fibroblast-derived type B cells; and type C cells, which appear to be an intermediate between A and B forms.^{7,9-11} The most abundant are the type B cells, which synthesize a variety of important macromolecules, including collagen and hyaluronan.^{12,13} The viscosity of synovial fluid is largely the result of the concentration and degree of polymerization of hyaluronan, which serves a vital function in soft tissue lubrication. Type A cells, comprising only 10% to 20% of the lining cells, are predominately phagocytic. However, apparently some overlap in function between the two principal cell types exists.^{14,15} Importantly, synoviocytes synthesize a variety of soluble mediators implicated in the pathogenetic events of OA, including cytokines (e.g., interleukin-1 [IL-1]),¹⁶⁻¹⁸ eicosanoids (e.g., prostaglandin E₂),^{19,20} and proteinases.²¹ That the synovial lining is capable of expressing these substances supports a role for the synovium in the pathogenesis of OA.

Deep to the synovial lining, the subsynovial region possesses a rich blood supply that is essential to generating synovial fluid, facilitates the exchange of nutrients and metabolic wastes of the synovium, and provides the sole source of nutrition to adult articular cartilage. Because of the specialized structure and functions of the synovial lining and subsynovial stroma, synovial blood flow is subject to a complex regulatory system involving extrinsic control and locally produced factors such as angiotensin II, endothelin-1, and nitric oxide.²

Periarticular Soft Tissues

The periarticular soft tissues include muscles, tendons, ligaments, and joint capsule. Muscles effect movement and, via complex reflexes, are vital to providing joint stability and protecting the joint from supraphysiological excursion. Muscle mass is more abundant near joints with a wide range of movement, such as the shoulder and the hip, and less so around joints that move in a single plane. Tendons serve as a bridge between muscle and bone, and ligaments provide stability between bones composing a joint. Tendons and ligaments are of similar, although not identical, composition, consisting mainly of water, an organized array of collagen bundles (predominantly type I), and a sparse population of fibroblasts. Ligaments contain more elastin fibers and have greater elasticity than tendons.²² Importantly, the molecular composition of these tissues responds to physical stimuli, and immobilization elicits catabolic events

leading to tissue weakening.²³ The composition of capsular structures parallels that of ligaments. Indeed, some ligaments can be recognized only as hypertrophied portions of the joint capsule. The fundamental role of the capsule is to provide stability; however, its specific nature varies with anatomical location and joint position. For example, the caudal capsule of the human knee is lax in flexion but exerts an important stabilizing force when the joint is in extension.²⁴

Subchondral Bone

Although subchondral bone is histologically and biochemically similar to bone in other locations, the organization of the subchondral plate is specific. The plate is thinner than cortical bone found at other locations, and its Haversian systems are oriented parallel to the joint surface rather than parallel to the long axis of the bone.²⁵ Similarly the organization of subchondral cancellous bone varies between joints, reflecting predominant biomechanical forces and adaptation to exercise.^{26,27} The deformability of the subchondral cortical and epiphyseal trabecular bone exceeds that of the diaphyseal cortical shaft by many times and has the important function of force attenuation. As such, possibly the bone stiffening (sclerosis) observed in OA contributes to disease progression.^{28,29}

Articular Cartilage

Cartilage is the principal working tissue of the joint and allows simultaneous motion and weight-bearing with negligible friction. Cartilage covers the subchondral plate of bones composing the joint, to which the cartilage is firmly attached. Its thickness varies between joints and at different locations within them. Cartilage is composed of water, collagen, and proteoglycans that are present in respective proportions of 65% to 80%, 10% to 30%, and 5% to 10% of its wet weight. Chondrocytes account for less than 2% of its volume in most species. In adults, cartilage is avascular, alymphatic, and aneural; thus cartilage is nourished mainly via the synovial fluid (see the following discussion). Because articular cartilage is aneural, lesions restricted to cartilage are nonpainful, and the innervation of the underlying bone and adjacent periarticular soft tissues is responsible for providing information on joint position.

Cartilage possesses a number of zones or layers including the following:

- The superficial (tangential or gliding) zone, in which the cells are elongated and oriented parallel to the joint surface
- A middle (transitional) zone, in which the cells are rounded and appear randomly distributed
- A deep (radial) zone, containing cells arranged in columns oriented perpendicular to the surface
- A calcified zone, in which cells are heavily encrusted with hydroxyapatite crystals (Figure 61-1)

The latter two zones are separated by an irregular line, visible on standard histological preparations, called the tidemark, the specific function of which is unclear.³⁰ The density of chondrocytes in the matrix varies with depth from the articular surface, as does the macromolecular composition of the matrix surrounding the chondrocytes. These regional differences can be identified histologically and have been designated as the pericellular, territorial, and interterritorial regions.

Fig. 61-1 • Photomicrograph illustrating regional organization of mammalian cartilage. The four main zones from the articular surface to the subchondral plate include the superficial (tangential) (S), the middle (transitional) (M), the deep (radial) (D), and the calcified (C) zones. The deep and calcified zones are separated by the tidemark (TM). Pericellular matrix regions, distinguishable by their histological and ultrastructural differences and located at progressively greater distances from chondrocyte lacunae, are the pericellular, territorial, and interterritorial regions (×50). SCB, Subchondral bone.

The unique functional properties of articular cartilage are reflected in its biochemistry. Articular cartilage is composed of an abundant, specialized extracellular matrix maintained by the aforementioned sparse population of chondrocytes (Figure 61-2). Its water content varies with age but may be as high as 80%.³¹ This water is freely exchangeable with that in the synovial fluid and is maintained in the matrix in the form of a gel, with matrix collagens and proteoglycans. Water movement is believed to be pivotal to the capacity of cartilage to absorb and distribute compressive load and for its lubrication.

Collagens

The collagens of articular cartilage differ from those found in most other locations in the body. Several collagens, fibrillar and nonfibrillar, are present in this tissue and are thought to provide cartilage with structural support. These proteins also interact with other matrix components to contribute to cartilage architecture and function.³²⁻³⁴ Collagen fibrils are oriented parallel to the joint surface in the superficial zone and act as a protective layer, whereas larger, radially oriented fibrils in the deeper layers anchor the cartilage to the underlying articular end plate.

Type II collagen is the most abundant in cartilage, accounting for about 90% of the fibrillar network and half of the dry weight of cartilage.^{2,35} Type II collagen consists of three identical amino acid chains arranged in a triple helix, is less soluble, possesses a higher proportion of hydroxylysine residues, and is more richly glycosylated

Fig. 61-2 • Organization of the major extracellular matrix components in articular cartilage. The principal collagen of cartilage is type II, and a network of these fibrils provides much of the tensile strength of the tissue. Aggrecan is composed of a linear protein with three globular domains (G_1 to G_3) to which are attached numerous glycosaminoglycan chains of chondroitin sulfate (CS) and keratan sulfate (KS) (see also Figure 61-4). Supramolecular aggregates are formed by the noncovalent interaction of aggrecan with hyaluronan (HA) and stabilized by link protein (Link). The negatively charged glycosaminoglycans (CS and KS) attract several times their weight in water, and this proteoglycan-water composite is responsible for the compressive stiffness of cartilage. Cartilage also has a number of minor proteoglycans and collagens (e.g., decorin and dermatan sulfate [DS], the functions of which are not fully characterized). Fragments of aggrecan, remaining bound to hyaluronan, are depicted to illustrate the effects of proteolytic activity in cartilage. (From Koopman WJ, editor: *Arthritis and allied conditions: a textbook of rheumatology*, ed 13, vol 1, Baltimore, 1997, Williams & Wilkins.)

Fig. 61-3 • Schematic representation of collagen fibril organization and its proteolytic degradation in cartilage. Cartilage collagen is arranged in fibrils of cross-linked, triple-helical molecules overlapping at regular intervals. Collagenases cleave intact helical collagen and produce characteristic $\frac{3}{4}$ - $\frac{1}{4}$ fragments. Other proteases (e.g., stromelysin) degrade collagen in nonhelical regions. (From Koopman WJ, editor: *Arthritis and allied conditions: a textbook of rheumatology*, ed 13, vol 1, Baltimore, 1997, Williams & Wilkins.)

than type I collagen.^{36,37} Unlike type I, which typically forms fibers, type II collagen is organized in the form of fibrils that are composed of molecules aligned with a 25% overlap or quarter stagger (Figure 61-3). This structure is stabilized by chemical bonds between specific amino acids in each chain, called hydroxyphenylpyridinium cross-links.³⁸ Fibrils are not uniform in size throughout the matrix; they tend to be larger in the middle and deep zones of the matrix, which reflects regional biomechanical demands.³⁹

This protein is arranged in arcades, which form the three-dimensional network or skeleton of the cartilage matrix. Type II collagen is produced by the chondrocytes, and whereas significant degradation and resynthesis of fibrils occur during growth and development, limited turnover occurs in adults.^{40,41}

Minor collagens are present in modest amounts in cartilage, and the specific roles of these collagens in its structure and function have yet to be defined fully. Type XI is

a fibrillar collagen that is found within type II fibrils. Its function is unclear, but likely it plays a role in type II collagen fibril assembly and organization because a mutation in the type XI gene in mice leads to a disorganized matrix, with abnormally thick collagen fibrils.⁴² Type VI is a microfibrillar collagen that may act as a bridge between fibrillar collagen and other matrix components.^{43,44} So-called fibril-associated small collagens include collagens IX, XI, and XIV. Type IX collagen molecules bound covalently to the surface of type II fibrils may serve to stabilize the latter.⁴⁵ Types XII and XIV collagen also are associated with fibrillar collagen, but the specific functions have yet to be identified.

Proteoglycans

By definition, proteoglycans are composite molecules consisting of protein and glycosaminoglycan (polysaccharide) components. This definition is broad because some of the aforementioned minor collagens (e.g., type IX) have a single glycosaminoglycan side chain and thus can be designated as proteoglycans. A number of proteoglycans are found in articular cartilage. Aggrecan, the largest and most abundant, has a well-defined function in the extracellular matrix; however, the specific roles of the smaller proteoglycans remain to be characterized fully.

Aggrecan is the primary proteoglycan of articular cartilage that interacts with hyaluronan to form aggregates (see Figures 61-2 and 61-3; Figure 61-4). The individual or monomeric form of this molecule consists of a linear core protein interrupted by three globular domains. The first of these globular domains is designated G₁, exists at the amino-terminal portion of the molecule, and is the site at which the proteoglycan attaches to hyaluronan. As many as 100 aggrecan monomers may be attached to the same hyaluronan chain to form supramolecular aggregates of

micrometer dimensions (see Figure 61-2).⁴⁶ The interaction of aggrecan with hyaluronan is noncovalent but is stabilized by a link protein that binds to the G₁ domain and hyaluronan with equal affinity.⁴⁷ Equine link protein was characterized and is similar to that found in human cartilage.⁴⁸ The specific functions of the G₂ and G₃ domains are unclear; however, because the G₃ domain is present in only about one third of the aggrecan monomers in adult cartilage, it is unlikely that it plays a pivotal role in the extracellular matrix.⁴⁹

In the region between the second and third globular domains, glycosaminoglycan chains of variable length and composition are attached radially to the protein core (see Figure 61-4). Immediately adjacent to the G₂ domain is a region rich in keratan sulfate, and this portion of the proteoglycan, detectable by monoclonal antibodies, has served as a tissue marker of matrix turnover.⁵⁰ Farther peripherally on the core protein is the chondroitin sulfate-rich region, where up to 100 chondroitin sulfate chains may be found attached radially to the core protein. These chondroitin sulfate chains vary in length, which is the main reason for heterogeneity in the size of aggrecan. Importantly, these glycosaminoglycan chains contain numerous carboxyl and sulfate groups, so that aggrecan is highly negatively charged and can bind up to 50 times its weight in water.^{46,51,52} This highly hydrated matrix gives cartilage its compressive stiffness and ability to dissipate load.

Matrix Proteins

Cartilage, like other connective tissues, contains a number of noncollagenous proteins, many of which are proteoglycans. Among the best characterized of the small proteoglycans are decorin, biglycan, lumican, and fibromodulin, all of which are similar in molecular organization. These proteins have been shown to interact with a number of matrix constituents, including cartilage collagens, and in many cases these interactions involve a number of different collagens and appear to regulate a variety of metabolic processes.^{46,52} For example, decorin and fibromodulin inhibit fibrillogenesis of type II collagen, a process that may regulate the size of collagen fibrils in the matrix.⁵³ Some of these small matrix proteins also may contribute to the antiadhesive properties of articular cartilage.^{54,55}

Cartilage also contains a number of small proteins that are neither collagens nor proteoglycans,^{56,57} and most are involved in interactions with a variety of matrix molecules and chondrocytes. For example, anchorin is found on the surface of chondrocytes and within the cell membrane and has a high affinity for type II collagen fibrils. These properties suggest that anchorin may act as a mechanoreceptor, providing chondrocytes with information on changes in stresses experienced by the matrix. Fibronectin is a minor component of cartilage that is thought to contribute to matrix assembly, via interactions with chondrocytes and elements of the extracellular matrix. Fibronectin fragments are present in elevated quantities in OA and may contribute to catabolic events in affected cartilage.^{58,59} Cartilage oligomeric matrix protein (COMP), also known as thrombospondin-5, is abundant in articular cartilage and is formed by the association of five identical subunits. COMP is most abundant in the proliferative cell layer of growth cartilage, where it is thought to regulate cell growth.

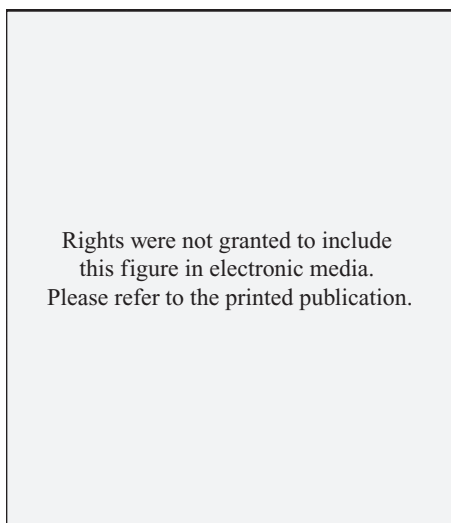

Fig. 61-4 • Schematic representation of an aggrecan monomer. Proteolytic cleavage of the molecule in vivo usually first occurs in the G₁ to G₂ interglobular domain (IGD). The specific sites involved vary among the enzymes implicated in the process. Keratan sulfate (KS) and chondroitin sulfate (CS) regions are positioned on the periphery of the molecule. (From Koopman WJ, editor: *Arthritis and allied conditions: a textbook of rheumatology*, ed 13, vol 1, Baltimore, 1997, Williams & Wilkins.)

Chondrocytes

Studies of cartilage metabolism contradict the seemingly inert histological appearance of this relatively acellular tissue. Despite the fact that chondrocytes represent a small percentage of the volume of cartilage, they are responsible for extracellular matrix synthesis, including all the collagens and proteoglycans. They are also capable of elaborating a variety of proteolytic enzymes effecting degradation of matrix macromolecules. The rate of turnover of the various matrix components is not uniform. At least a portion of the proteoglycan pool is renewed at a relatively rapid rate, whereas the rate of collagen turnover is minimal.⁶⁰⁻⁶² Chondrocyte metabolism is influenced by intrinsic and extrinsic mechanical influences. For example, cyclic loading and alterations in matrix pressure, as a result of changes in solute content, materially influence proteoglycan synthetic rates.^{63,64} Thus the maintenance of the cartilage matrix involves the chondrocyte-mediated processes of synthesis and degradation, and the cartilage loss in OA appears to be attributable to a disequilibrium in favor of matrix degradation.

Nutrition

Unlike the cartilage of growing animals, in which articular cartilage receives some blood supply from subchondral vasculature, adult articular cartilage contains no blood vessels. As a result, the chondrocyte exists under relatively hypoxic and acidic conditions, with an extracellular pH typically 7.1 to 7.2.⁶⁵ Nutrients migrate from subsynovial vessels to the synovial fluid and subsequently penetrate the dense connective tissue matrix of the cartilage, while metabolic wastes are simultaneously cleared in the opposite direction. The density of the matrix appears not to hamper diffusion because molecules as large as hemoglobin (65 kDa) can penetrate normal articular cartilage.⁶⁶ The highly charged proteoglycans contained in the matrix do not inhibit the diffusion of small, uncharged molecules.⁶⁷ Entry of solutes into the matrix occurs by simple diffusion or may be facilitated by compression-relaxation cycles. Intermittent loading of cartilage is vital to its health, as is evidenced by the deleterious effects of immobilization.⁶⁸

Joint Lubrication

Although several mechanisms for cartilage-on-cartilage lubrication have been hypothesized, two main systems are accepted: a hydrostatic or weeping system that functions at high loads, and a boundary system that functions at low loads.⁶⁹ Hydrostatic lubrication of opposing cartilaginous surfaces is effected by a thin film of water liberated from the matrix during cartilage compression. Because little movement of water can occur from cartilage to the subchondral bone, most is squeezed from the opposing cartilages onto the surface, immediately peripheral to the zone of impending contact.⁷⁰ With the release of compressive force, the cartilage expands, and water is drawn back into the matrix.

Whereas hydrostatic mechanisms function well under relatively heavy loads, boundary lubrication occurs under low-load conditions. Boundary lubrication is accomplished by specialized materials including lubricin⁷¹ (a glycoprotein of synovial origin) and hyaluronan. These molecules bind to opposing articular cartilage surfaces and prevent the direct contact of these surfaces under low loads.

Coefficients of friction were unchanged after hyaluronidase treatment of synovial fluid, suggesting that hyaluronan has no place in cartilage-on-cartilage lubrication.^{72,73} However, others have found that hyaluronan actually does function as a boundary lubricant.^{74,75}

Articular soft tissues require lubrication because they contribute most of the frictional resistance to joint movement. Indeed, the energy requirement for the stretching of articular soft tissues is 100 times that of the frictional resistance of opposing cartilage surfaces.⁷⁶ The synovium is lubricated by a thin film of synovial fluid, rich in hyaluronan, its principal boundary lubricant.⁷⁷

Intraarticular Volume and Pressure

Intraarticular volume varies and is influenced by joint position (see Chapter 66). Specifically, volume and pressure are respectively minimal and maximal near the extremes of flexion and extension.⁷⁸⁻⁸¹ This effect is exacerbated in horses with synovial effusion, providing a physiological rationale for diagnostic flexion tests in equine lameness examinations. Moreover, the pointing of an equine limb in which there is joint effusion likely parallels the observation that in the human knee there is a maximum of intraarticular volume (and minimum of intraarticular pressure and pain) at 30 degrees of flexion.^{82,83}

Whereas intraarticular pressure varies during movement, pressure within a normal joint is subatmospheric at rest.^{84,85} As a result, the normal synovial cavity is merely a potential space, the surfaces of which are coated with a thin film of synovial fluid to reduce friction during movement. Although the mechanisms by which this negative pressure occurs remain unclear, the phenomenon contributes measurably to joint stability.⁸⁶ Lack of familiarity with the physiological concept of negative intraarticular pressure in normal joints results in the common misconception that the sound of air being aspirated into a joint during arthrocentesis heralds a dry or diseased joint.

Biomechanical Considerations

Articular cartilage remains healthy despite being regularly subjected to considerable normal and shear forces during normal activities. A number of mechanisms exist to facilitate this phenomenon, including the transmission of forces to surrounding tissues by periarticular soft tissues, the incongruity of cartilage surfaces, and the inherent compliance of cartilage and subchondral bone. Indeed, the capacity for considerable elastic deformation permits normal cartilage to withstand compressive stresses considerably greater than those of body weight alone.^{87,88} Nonetheless, cartilage is subject to mechanical breakdown after supra-physiological stresses, and loads exceeding 25 kg/cm² are reported to result in matrix damage.⁸⁹ Apparently these loads occur in specific areas of cartilage under a variety of clinical circumstances, such as the cartilage degeneration that accompanies the incongruent articular surfaces of a poorly reduced or unstable intraarticular fracture.

At the tissue level, the ability of cartilage matrix to resist compression and shear is a function of the interaction of collagen, aggrecan, and tissue fluid. Aggrecan can absorb many times its weight in water, but its complete hydration is restricted by the collagen network. Thus a balance exists between the internal swelling pressure exerted by the association of water with aggrecan (Gibbs-Donnan ionic

equilibrium) and the tensile forces of the collagen fibrils. Cartilage under load undergoes a two-phase (viscoelastic) deformation.^{90,91} Initially rapid bulk movement of water from the matrix and compression of collagen occur. Subsequently, a time-dependent compression occurs, known as the creep phase, in which water flows through the matrix at a slower rate.

These mechanical phenomena were studied in experiments evaluating the mechanical properties of cartilage after the selective depletion of specific matrix components. The tensile strength of cartilage is a function of its type II collagen content because strength is reduced in collagen-depleted tissues but is unaffected by proteoglycan removal.^{92,93} Proteoglycans (mainly aggrecan) provide the matrix with its compressive stiffness and protect the collagen network from mechanical damage. Trypsin-treated (proteoglycan-depleted) specimens lose the ability to rebound from compressive load and have reduced stiffness.⁹⁴

At rest, opposing articular surfaces are not completely congruent, but when loaded, articular cartilage contact increases, which serves to distribute stress and increase joint stability. This may be a physiological reason why cartilage tends to be somewhat thicker in less congruous joints, such as the hip and stifle.⁹⁵ Although cartilage is designed to withstand compressive stress, its ability to act as a shock absorber is finite, largely because it receives its nutrition by diffusion and as a result is of limited thickness. Because its ability to absorb load is limited, cartilage must transmit load to the underlying subchondral bone. As such the articular ends of most bones are flared (less force per unit area) and deform under physiological load to absorb stress.⁹⁶ Noteworthy is that the stiffness of the subchondral bone is attributable not only to the cancellous trabeculae but also to the extracellular fluid content. This was demonstrated in an experiment where subchondral stiffness of canine femoral heads was reduced by 30% after fluid decompression by drilling.⁹⁷ When the subchondral bone is unable to accommodate loading, so-called adaptive remodeling failure occurs, in which repetitive subchondral deformation causes trabecular microfractures, which may or may not be accompanied by changes in articular cartilage. Fortunately, when occurring at an acceptable rate, trabecular microfractures undergo a reparative response leading to an orientation of subchondral bone that provides improved strength and shock absorption capacity.⁹⁸ Articular surfaces are protected by stress distribution mechanisms beyond those of cartilage and bone. For example, muscles absorb a large proportion of the force experienced during impact loading, leaving the remainder to be cushioned by cartilage and bone. Fine-tuned neuromuscular reflexes are required for this system to work effectively, and small failures in these reflex arcs lead to insufficient attenuation of impact loading, which may lead to degenerative changes in cartilage and subchondral bone.⁹⁹

OSTEOARTHRITIS

Etiopathogenesis

OA has been defined as an essentially noninflammatory disorder of movable joints, characterized by degeneration and loss of articular cartilage and the development of new bone on joint surfaces and margins.^{36,100} As in people,

equine OA is probably not a single disease but reflects a common response of joint tissues to a number of potential causes. Unfortunately the specific contributions and interactions of various mechanical and biological factors contributing to development of OA lesions remain unclear.

Three pathogenetic mechanisms are hypothesized for OA.¹⁰⁰ The first involves a fundamentally defective cartilage, with abnormal biomechanical properties. In this pathway a biomechanically flawed matrix fails under normal loading. In people a type II collagen defect exemplifies this primary form of OA.^{101,102} OA attributed to inherently defective cartilage matrix components has not yet been identified in the horse.

A second proposed pathogenetic pathway of OA involves physical changes in the subchondral bone.^{28,29} Because articular cartilage is too thin to be an effective shock absorber, impact loading must be attenuated by peri-articular soft tissues, muscles, and subchondral bone. Although substantially stiffer than cartilage or joint capsule, cancellous subchondral bone is considered an important shock attenuator. Thus in this hypothesis of OA pathogenesis, normal mechanical stresses result in microfractures of the subchondral and epiphyseal trabecular bone. However, when occurring at an excessive frequency, these fractures exceed the rate at which optimal healing and remodeling of the subchondral trabeculae can occur. Bone accretion with healing of these microfractures increases the density of the subchondral plate and adjacent trabeculae, with a concomitant reduction in the ability to absorb repetitive physiological loads. The resulting increase in bone stiffness leads to a state in which the bone-cartilage unit fails to deform normally under load, and the cartilage experiences supraphysiological stresses, resulting in mechanical damage. Subsequent events are those outlined in the following discussion of the third pathogenetic mechanism of OA.

To date, a cause-and-effect relationship between subchondral bone plate thickening and cartilage degeneration remains to be established. The hypothesis that subchondral bone and cartilage degeneration are related is supported by the demonstration of microfractures of the subchondral plate and more distant trabeculae in arthritic specimens.¹⁰³ Moreover, in mice with OA, cartilage degenerates over areas of sclerotic bone but remains intact over areas of normal bone density.¹⁰⁴ However, mathematical models predict that even with considerable increases in subchondral bone stiffness, cartilage stresses are only modestly increased.¹⁰⁵ Collectively these data indicate that subchondral sclerosis contributes to the osteoarthritic process but is probably not a prerequisite to initiate articular cartilage destruction.¹⁰⁶

The third and most popular hypothesis of the pathogenesis of OA is based on the concept of mechanical forces causing damage to healthy cartilage.^{36,52,100,107} Matricial or cellular injury by these forces results in metabolic alterations of chondrocytes, leading to the release of proteolytic enzymes that cause cartilage fibrillation and breakdown of the proteoglycan network. Cartilage is remarkably resistant to shear forces but is relatively susceptible to repetitive impact trauma. In people, repetitive trauma is an acknowledged predisposing factor to OA in athletes (e.g., metacarpophalangeal joints of boxers) and certain occupations (e.g., shoulder joints of jack-hammer operators). Of many

potential causes, repeated microtrauma (use trauma) is probably the most common pathogenetic factor in equine OA, and the correlation of lesions at defined sites in horses participating in specific sports supports this hypothesis.

Role of the Synovium

Although conventional concepts of OA emphasize the direct and predominant involvement of cartilage and bone in OA development, it is increasingly recognized that the synovium contributes to the central pathophysiological event of cartilage matrix depletion. Recent investigations in several species have shown that synoviocytes are a rich source of a variety of inflammatory mediators and degradative enzymes implicated in cartilaginous degeneration, including prostaglandins,^{19,20,108-111} cytokines,¹¹²⁻¹¹⁴ and matrix metalloproteinases (MMPs).¹¹³⁻¹¹⁶ These laboratory data are supplemented by the identification of increased levels of these and other inflammatory mediators in the synovial fluid of horses with naturally occurring or experimentally induced synovitis.¹¹⁷⁻¹²⁴ Experiments using synovially conditioned culture media, or cocultivation of synovial tissues with cartilage, support a role of the synovial membrane in cartilage degradation.^{125,126} Recent experiments indicate that synovial macrophages are important contributors to the inflammatory and degradative responses in affected joints, effects mediated by a combination of IL-1 and tumor necrosis factor- α (TNF- α) (see Cytokines discussion).¹²⁷ Nonetheless, determining the specific role of the synovium in OA is hampered by the fact that both chondrocytes and synoviocytes are a rich source of the pertinent mediators and enzymes. Thus precise characterization of the relative quantitative and temporal contributions of cartilage and synovium to lesion development has not yet been accomplished.

Role of the Chondrocyte

Of all joint tissues, articular cartilage shows the greatest aberration from normal during disease development, and it is generally considered that metabolic changes in chondrocytes play a primary role in the pathophysiological events of cartilage loss. In normal joints, chondrocytes are responsible for maintaining a balance between matrix degradation and repair, and this equilibrium is maintained by a complex interaction between chondrocytes, cytokines, and mechanical stimuli.¹²⁸ In OA, a disruption of this homeostatic state develops, in which catabolic processes predominate. Although proteoglycan synthesis is greater than normal early in the disease, the rate of matrix digestion is sufficient that the result is a net loss of matrix. With this imbalance toward matrix depletion, cartilage mass is progressively lost, and the viscoelastic properties of the remaining tissue become insufficient to withstand normal loads. Subsequently, cartilage fissuring and separation occur (Figure 61-5). The ultimate result is generalized cartilage loss and secondary remodeling of bone and articular soft tissues (Figure 61-6).

A number of studies indicate that an important initial biochemical change in OA is the loss of aggregating proteoglycans. Up-regulation of chondrocyte proteoglycan synthesis is insufficient to offset enhanced degradation, so that the concentration in the matrix progressively decreases. In addition to a reduced quantity of proteoglycan, the quality of molecules remaining in the matrix, and newly

Fig. 61-5 • Photomicrograph illustrating the pathological changes associated with cartilage matrix degeneration. Loss of matrix proteoglycans alters the biomechanical properties and ultimately leads to fissures (*Fiss*) in the cartilage, in this case a full-thickness fissure. Chondrocyte clones (*cl*) represent the abortive healing attempts of chondrocytes ($\times 50$).

Fig. 61-6 • Post mortem specimen of the distal aspect of an equine third metacarpal bone illustrating partial and full-thickness cartilage loss. Although osteoarthritis affects all articular tissues, degeneration of extracellular matrix of cartilage and its subsequent loss are considered the central events in the disease. Note also the wear lines on the articular cartilage.

synthesized replacements, appears to be altered.^{129,130} Collagen degradation accompanies proteoglycan loss and is manifested by surface fibrillation (Figure 61-7). The loss of collagen and changes in collagen fibril size contribute to weakening of the matrix and may account for the increased water content in early cartilage lesions.¹³¹⁻¹³³

Whereas degradation of articular cartilage may occur by the action of a number of mediators, including oxygen-derived free radicals,¹³⁴⁻¹³⁷ proteolytic enzymes synthesized

Fig. 61-7 • Arthroscopic endophotograph of the middle carpal joint of a Standardbred racehorse with a large osteochondral fragment of the third carpal bone (top) and concomitant lesions of the intermediate carpal bone (bottom). Cartilage fibrillation is substantial, and its evaluation is greatly facilitated by fluid distention of the joint. Fibrillation indicates damage to the collagenous network of the extracellular matrix.

by chondrocytes are thought to be the major mediators of matrix depletion. Proteinases are classified according to the catalytic mechanism into four main groups, including aspartic proteinases, cysteine proteinases, serine proteinases, and metalloproteinases. Members of each class are synthesized by chondrocytes or synoviocytes and may contribute to cartilage degradation. However, the MMPs and related enzymes apparently are the most active in OA.^{36,52,138-140} Chondrocytes have surface receptors that respond to mechanical stress, and physical disruptions of cell-matrix associations can negatively influence chondrocyte synthetic activities.¹⁴¹

Matrix-Degrading Enzymes

MMPs are considered to play a major role in cartilage matrix degradation in OA because this group of proteinases is capable of digesting all major components of the extracellular matrix. The relative contributions of these proteolytic enzymes to the overall process remain to be firmly established; however, a wealth of evidence implicates them in cartilage loss. Specifically, MMPs are synthesized by synoviocytes and chondrocytes^{21,52,142-144} and are present in increased concentrations in diseased cartilage,^{145,146} and the topographical distribution and concentration of MMPs in cartilage are correlated with the histological severity of lesions.¹⁴⁶⁻¹⁴⁸ Several types of MMPs are expressed by articular tissues, and these are classified as collagenases, stromelysins, gelatinases, membrane-type metalloproteinases, and other MMPs.¹⁴⁴ In addition to other substrates, collagenases degrade intact, helical type II collagen. Stromelysins cleave partially degraded collagen, proteoglycans, and other minor proteins in cartilage. The gelatinases have a diverse range of substrates, including partially degraded type II collagen and types X and XI collagen and elastin. Like collagenases, membrane-type 1 MMP is also capable of digesting fibrillar collagen and a number of other matrix components. MMPs

are secreted in an inactive or latent form and require activation through proteolytic cleavage. A variety of enzymes including trypsin, chymotrypsin, plasmin, kallikrein, cathepsin B, and certain MMPs themselves are capable of such cleavage.^{52,138,148} The classification and general properties of MMPs are summarized in Table 61-1.

Several members of the ADAM (*a disintegrin and metalloproteinase*) family of enzymes were shown to be expressed by chondrocytes.^{149,150} Many of the ADAM enzymes are proteinases and are structurally and functionally related to MMPs. Importantly, certain members of this group cleave aggrecan at a specific site in the interglobular (G₁ to G₂) domain, resulting in aggrecan fragments identical to those found in the tissues and synovial fluids of osteoarthritic animals. These proteinases have been termed *aggrecanase* and share many similarities to typical MMPs, including the inactivation with conventional MMP inhibitors and being inhibited by tissue inhibitor of matrix metalloproteinase-1 (TIMP-1).¹⁵¹ Two forms of aggrecanase have been implicated in OA, and both are ADAMTS enzymes (ADAM with thrombospondin type 1 motifs).^{152,153} (The thrombospondin subunits of the protein appear to be critical for the binding and digestion of aggrecan.¹⁵⁴) ADAMTS4 and ADAMTS5 (aggrecanases 1 and 2, respectively) are related enzymes but demonstrate important differences in their regulation by cytokines. For example, although ADAMTS4 is induced by cytokines and ADAMTS5 appears to be constitutively expressed, both are implicated in aggrecan degradation in OA.¹⁵⁵ Aggrecanase is considered pivotal in proteoglycan degradation. Indeed, some contend that aggrecanase is the principal mediator of proteoglycan depletion in OA.¹⁴⁰

In healthy cartilage, the activity of proteolytic enzymes is controlled by a number of mechanisms, one of which is naturally occurring inhibitory proteins. The most important of these inhibitors are the TIMPs.^{52,137,144,156} Synthesized by synoviocytes, chondrocytes, and endothelial cells, TIMPs inactivate MMPs by binding to them in a 1:1 non-covalent complex,¹⁵⁷ and these inhibitors are hypothesized to be critical to the longevity of the extracellular matrix of cartilage.^{148,158} TIMP exists in at least four forms, the first three of which (TIMP-1, TIMP-2, TIMP-3) are expressed by chondrocytes. Interestingly, each is subject to somewhat different regulatory mechanisms.^{159,160} The important role of TIMPs in cartilage matrix health is supported by the observation that imbalances in the ratio of MMP to TIMP synthesis in cartilage are important determinants of the rate of matrix degradation.^{148,161}

Cytokines

Cytokine is a general term to describe a broad array of small regulatory proteins produced by a variety of cells in the body. In joints, these mediators exist in a complex balance of activities that regulate the metabolism of the synovial membrane, bone, and articular cartilage in health and disease (Table 61-2).^{162,163} Numerous cytokines are involved in articular metabolism, and they possess one or more pro-inflammatory (catabolic), anti-inflammatory (regulatory), or anabolic functions. Important in OA are the proinflammatory cytokines, such as IL-1 and TNF- α . Chondrocyte receptors for IL-1 and TNF- α are up-regulated in osteoarthritic cartilage, and the activation of these receptors has several deleterious effects on chondrocyte metabolism.^{164,165}

TABLE 61-1

Matrix Metalloproteinases Implicated in Cartilage Matrix Degradation		
PROTEINASE*	MMP	CARTILAGE SUBSTRATES
Collagenases		
Interstitial collagenase (collagenase) [†]	MMP-1 [‡]	Collagens II and X (not IX and XI), denatured type II, aggrecan, link protein
Neutrophil collagenase [†]	MMP-8	Collagen II, aggrecan, link protein
Collagenase 3 ^{‡§}	MMP-13 [‡]	Collagens II, IV, IX, X; aggrecan; fibronectin
Stromelysins		
Stromelysin 1 [†]	MMP-3 [‡]	Aggrecan, fibronectin; denatured collagen II; collagens IV, IX, X, XI; procollagens; link protein; decorin; elastin; laminin
Stromelysin 2 [†]	MMP-10	Same as for stromelysin 1
Gelatinases		
Gelatinase A (72 kD) [†]	MMP-2 [‡]	Denatured collagen II, collagens X and XI, elastin
Gelatinase B (92 kD) [†]	MMP-9 [‡]	Aggrecan, fibronectin, collagens IX and XI, procollagens, link protein, decorin, elastin
MT-MMPs		
MT1-MMP [†]	MMP-14	Aggrecan, collagen II, denatured collagen II, fibronectin, laminin
Others		
Matrilysin (PUMP) [†]	MMP-7	Aggrecan
Stromelysin-3	MMP-11	Proteoglycan, denatured collagen II, fibronectin, laminin
Macrophage metalloelastase	MMP-12	Elastin
Novel MMP	MMP-19	Denatured collagen II, collagen IV, aggrecan, fibronectin, laminin

MMP, Matrix metalloproteinase; MT(1)-MMP, membrane-type (1) matrix metalloproteinase; PUMP, putative metalloproteinase.

[†]All except membrane-type 1 MMP are inhibited by some or all of the tissue inhibitors of metalloproteinases 1 to 3.

[‡]Expressed by chondrocytes. All are expressed in synovium.

[§]MMPs characterized in the horse.

[§]MMP-13 expression is relatively weak in equine synovium.

TABLE 61-2

General Classification of Cytokines and Their Actions on Cartilage Metabolism		
CATEGORY OF CYTOKINE	EXAMPLES	ACTIONS
Catabolic (pro-inflammatory) cytokines	IL-1, TNF α	Promote MMP synthesis Promote nitric oxide and PGE ₂ production Inhibit collagen II and aggrecan synthesis
Modulatory (regulatory) cytokines*	IL-4, IL-6, IL-10, IL-13	Stimulate TIMP synthesis Promote IRAP synthesis Inhibit IL-1 synthesis
Anabolic cytokines (growth factors)	IGF-1, TGF- β , bFGF	Promote collagen II synthesis Promote proteoglycan synthesis

IL, Interleukin; TNF, tumor necrosis factor; MMP, matrix metalloproteinase; PGE₂, prostaglandin E₂; TIMP, tissue inhibitor of matrix metalloproteinase; IRAP, interleukin-1 receptor antagonist protein;

IGF, insulin-like growth factor; bFGF, basic fibroblast growth factor.

*Regulatory cytokines can have mixed actions (e.g., IL-6 amplifies IL-1 effects on MMP synthesis but induces TIMP synthesis).

A wealth of recent research suggests that IL-1 is the most important of the proinflammatory cytokines in OA. Early studies using cartilage organ culture provided data supporting a role for IL-1 in cartilage matrix degradation,¹⁶⁶ which were supplemented by the identification of elevated levels of this cytokine in synovial fluids of affected patients, including horses.^{119,120} IL-1 is involved in the destruction of the extracellular matrix and formation of the functionally inadequate repair tissue in arthritic cartilage. IL-1 decreases the synthesis of proteoglycans and type II collagen and induces the synthesis and secretion of proteolytic enzymes that degrade these matrix macromolecules.¹⁶⁷⁻¹⁷⁷

Decreased synthesis of matrix macromolecules occurs in cartilage exposed to IL-1 concentrations substantially less than those required to stimulate matrix degradation.¹⁶⁹ Catabolism is further promoted by inhibition of the synthesis of MMP inhibitors such as TIMP.¹⁷⁸ In addition, IL-1 stimulates the synthesis of prostaglandin E₂ and nitric oxide, the effects of which are outlined in the following discussion.¹⁷⁹⁻¹⁸³ IL-1 may also contribute to the proliferative events in OA. Osteophytosis may be caused, at least in part, by the stimulation of osteoblast-like cells by IL-1.¹⁸⁴ Perhaps the most compelling evidence supporting the involvement of IL-1 in OA is the protective effect of IL-1

receptor antagonist protein, which blocks many of the catabolic events typical of IL-1 *in vitro*. This naturally occurring competitive antagonist of IL-1 was shown to be protective for OA-like lesions in arthritis models.¹⁸⁵⁻¹⁸⁷

TNF- α is another proinflammatory cytokine that was implicated in the development of osteoarthritic lesions and was found in elevated concentrations in inflamed and arthritic joints.¹⁸⁸⁻¹⁹¹ Like IL-1, this cytokine stimulates the synthesis of matrix-degrading enzymes¹⁷⁵ and inhibits chondrocyte synthesis of proteoglycan and collagen.¹⁷⁶ TNF- α appears to be less potent than IL-1¹⁹²; however, the effects of IL-1 and TNF- α are potentiated when combined.¹⁹³ TNF- α appears to stimulate the synthesis of IL-1.¹⁹⁴ Experiments with adenoviral transfers of the gene expressing an endogenous inhibitor of nuclear factor κ B (IkB α) indicate that a substantial proportion of synovially derived inflammatory mediators and degradative enzymes are regulated by the nuclear factor κ B (NF κ B) pathway.¹⁹⁵

The degradative effects of certain cytokines, including IL-1 and TNF- α , are balanced by inhibitory cytokines (e.g., IL-4, IL-10, and IL-13). Moreover, opposing effects on matrix synthesis are induced by other cytokines, also known as growth factors (e.g., insulin-like growth factor and basic fibroblast growth factor) (see Table 61-2). Using these antiinflammatory and inhibitory cytokines to control the osteoarthritic process is an active area of research.

Nitric Oxide

Nitric oxide is another mediator of the pathophysiological events in OA. This highly reactive, cytotoxic free radical is a byproduct of the oxidation of L-arginine to citrulline, catalyzed by a group of enzymes called nitric oxide synthases (NOSs), which produce large amounts of the mediator when cells expressing this enzyme are activated by mediators such as endotoxins and cytokines.^{182,183,196} Early evidence for the involvement of nitric oxide in rheumatic diseases was the observation that nitrite, a stable end product of nitric oxide, was found in elevated concentrations in the synovial fluid and serum of people with rheumatoid arthritis.¹⁹⁷ Subsequently, it has been shown that osteoarthritic cartilage spontaneously produces nitric oxide.¹⁹⁸⁻²⁰⁰ Nitric oxide may mediate the inhibition of chondrocyte synthetic activities that occur in OA. Proteoglycan and type 2 collagen synthesis are inhibited under conditions conducive to nitric oxide formation.²⁰¹⁻²⁰³ Thus, like other inflammatory mediators, inducible NOS is stimulated by IL-1 and TNF- α and requires NF κ B for its expression.²⁰⁴

Nitric oxide also is hypothesized to mediate, in part, the augmented expression and activation of MMPs,^{205,206} as well as the reduced synthesis of the natural IL-1 receptor antagonist protein,¹⁹⁹ and is reported to be an important inducer of chondrocyte apoptosis.²⁰⁷ However, the specific role of nitric oxide in IL-1-induced cartilage matrix depletion is controversial. Early laboratory studies revealed that the MMP activity in IL-1- and TNF- α -stimulated cartilage cultures was enhanced by adding substrates favoring nitric oxide formation (nitric oxide donors), and this effect was blocked by NOS inhibitors.^{205,206} Conversely, cytokine-mediated induction of MMP expression can occur independently of stimulation by nitric oxide,²⁰⁸ and cytokine-stimulated cartilage explants cultured in the presence of nitric oxide inhibitors had rates of proteoglycan depletion comparable with controls.²⁰⁹ Nonetheless, nitric

oxide remains an important area of study, because in animal models of inflammatory arthritis and OA, using compounds that directly or indirectly inhibit NOS activity reduces the severity of lesions.²¹⁰⁻²¹³

Prostaglandins

Prostaglandins are found in elevated concentrations in inflamed joints,^{188,214} and although the specific effects of prostaglandins on joint metabolism are unclear, it is widely held that prostaglandin E₂ contributes to the lesions of OA. Prostaglandin E₂ causes synovial inflammation and may contribute to cartilage matrix depletion^{215,216} and the erosion of cartilage and bone.²¹⁷ Certain data indicate that prostaglandins may actually modulate the release of metalloproteinases, such as collagenases and stromelysins.^{218,219} Conversely, increasing evidence suggests that cytokine and MMP expression in articular cells is regulated by E-series prostaglandins.^{20,220} The net effect of this regulation is unclear because, like corticosteroids, prostaglandin E₂ appears to inhibit TIMP synthesis and MMP synthesis.²²¹ Moreover, some of the effects of prostanoids may be indirect, acting by promoting the synthesis of other proteins that have unique influences on cartilage metabolism.²²² Thus although prostanoids are a factor in the signs and certain of the pathophysiological processes of OA, the specific role in regulating cartilage depletion and the interactions with other mediators of cartilage lesion development requires elucidation.

Clinical Evaluation of Joint Disease

Joint Pain

Traumatic arthritis and OA may be the most common cause of lameness in equine athletes of all types. Unfortunately, there is a weak correlation between the magnitude of pain and the severity of articular damage observed.²²³⁻²²⁵ The hallmark of OA is articular cartilage degeneration, a process occurring in a tissue devoid of sensory innervation. As a result, lameness is typically attributed to involvement of periarticular soft tissues and bone, the former being relatively richly innervated. In capsular and ligamentous tissues, unmyelinated sensory nerve fibers conduct painful sensations from widely distributed free nerve endings.^{226,227} With joint inflammation, these receptors exhibit increased sensitivity. Specifically the threshold for these receptors is reduced by inflammatory mediators such as prostaglandins, and increased receptor activity accompanies physiological joint excursions.²²⁸ Although the severity of soft tissue changes and lameness are related,^{229,230} horses with substantial periarticular fibrosis occasionally demonstrate less than the expected degree of lameness. Studies of joint capsule innervation in arthritic specimens revealed that with time degeneration of neurons is common, which provides a potential reason for the less than expected magnitude of pain in some horses having clearly demonstrable changes in periarticular soft tissues.

Bone and periosteum also contribute to pain observed in horses with OA. The periosteum is well innervated, and the periosteal disruption that accompanies the development of periarticular osteophytes is a source of joint pain.²³¹ The subchondral plate and epiphyseal trabecular bone make variable contributions to clinical signs. For example, many, but not all, horses with subchondral cystic lesions

demonstrate lameness.²³²⁻²³⁴ Inconsistent lameness among horses with similar radiological signs parallels the weak correlation between pain and radiological findings of early OA in people.^{235,236} Osseous receptor stimulation often accompanies joint movements that cause elevations in intramedullary pressure. People with OA of the hip have elevated intraosseous pressure,²³⁷ which in some people responds favorably to cortical fenestration. Elevation in intramedullary pressure occurs with flexion or extension of equine joints and is a likely source of articular pain in some horses. For example, both simulated effusion and metatarsophalangeal joint flexion increase intramedullary pressure in the third metatarsal bone.²³⁸ The concept also is supported by the clinical observation of a favorable response to transcortical decompression in horses with lameness related to osseous cystlike lesions.

Magnetic resonance imaging (MRI) has been used to try to characterize osseous lesions associated with pain in people with OA. For example, one study demonstrated a correlation between knee pain and the presence of poorly marginated areas of increased signal intensity (T₂-weighted images).²³⁹ These areas of increased signal intensity, corresponding to fluid, have been termed "marrow edema." Unfortunately, the fluid comprising them has not been identified in correlative histological examinations.²⁴⁰⁻²⁴²

Local Signs

Limited range of motion is a common feature of equine OA and is probably caused by a combination of factors, including guarding from pain, synovial effusion and edema, and progressive periarticular fibrosis. Synovial edema and proliferation and pain are probably the main causes of reduced range of motion in horses with early OA, whereas fibrosis is important in chronically affected horses. The specific mechanisms causing periarticular fibrosis are unclear. However, cytokines and neuropeptides are likely to contribute to fibrosis, given the mitogenic effects on fibroblasts of these substances.²⁴³⁻²⁴⁵

Effusion is a common feature of OA and is manifested in joints in the distal aspect of equine limbs as visible or palpable distention of joint pouches. Leakage of protein into the synovial space, because of increased permeability in the capillary endothelium and intercellular spaces of the synovium, which is not matched by compensatory increases in lymphatic clearance, leads to a progressively increased colloid osmotic pressure and augmented synovial fluid volume. Although mild effusion enhances nutrient exchange in the joint,²⁴⁶ severe effusion results in progressively elevated intraarticular pressure that ultimately destabilizes the joint and causes pain, stiffness, and a reduced range of motion. Increased permeability of the synovium to cells and proteins varies with the degree of synovial inflammation and is reflected in cytological findings in synovial fluid samples.

Synovial Fluid Changes

Reduced viscosity of synovial fluid is a frequent finding in horses with OA, particularly in horses with active synovitis. Reduced viscosity has been attributed to a reduced concentration, or depolymerization, of synovial fluid hyaluronan. Substantial reductions in hyaluronan concentration have been documented in the synovia of horses with chronic traumatic arthritis²⁴⁷; however, considerable variability

exists. In a study comparing the hyaluronan concentration in normal horses with those having lameness that could be eliminated by intraarticular analgesia, normal horses had a mean hyaluronan concentration approximately 50% higher than that of horses with synovitis. However, the variability between horses was sufficient that this difference was not statistically significant.²⁴⁸ Clinical determinations of hyaluronan concentration are not routine because of this variability and the technically involved procedures required for the quantitative determination of hyaluronan. The mucin clot test is a relatively simple, semiquantitative test of hyaluronan quantity and quality, but it is not particularly sensitive. Therefore the quality of hyaluronan is often determined clinically by assessing viscosity on gross inspection of synovial fluid obtained during arthrocentesis.

Because increases in cell numbers and protein concentration in OA are not dramatic, cytological evaluation of synovial fluid is not used routinely diagnostically. Cytological analysis of synovial fluid is most useful in identifying and monitoring infection and untoward postinjection reactions. Approximate values for cell count and total protein concentrations under a variety of clinical situations are given in Table 61-3. Total protein concentration varies between joints, tending to be considerably higher in the larger, more proximal joints, such as the scapulohumeral joint.

Role of Radiography/Radiology

Radiography has long been the traditional means of assessing the structural changes of OA (see Chapter 15). Radiography has the advantages of availability, convenience, relative safety, and economy. Indeed, it is standard practice for many veterinarians to localize lameness to a particular area of the limb and subsequently to obtain radiographs in an attempt to identify changes to support a diagnosis of OA. Despite the advantages of superior contrast resolution and options for postprocessing image enhancement that accompany advances in digital radiography, the technique still lacks sensitivity and is of limited value in identifying horses with incipient or focal lesions. Radiology does, however, have some merit in characterizing changes in bone that accompany chronic OA and can be useful in adding confidence to the diagnosis of established disease. Nevertheless, it should be recognized that radiologically undetectable performance-limiting lesions occur in horses.^{257,258}

Radiological findings tend to witness past events in the pathological process and do not consistently reflect ongoing processes. Additionally, in horses, as has been long accepted in people, a lack of correlation exists between lameness or reduced performance and specific osseous structural changes evident radiologically.²⁵⁹⁻²⁶³ A lack of correlation with arthroscopically evident degeneration and radiological findings is also common.²⁶⁴⁻²⁶⁷ In addition to this underlying fundamental biological dichotomy, precise quantification of radiological findings is hampered by difficulties in precisely duplicating conditions from one radiographic examination to the next. Positioning, degree of weight bearing, and radiographic technique contribute measurably to results. Nonetheless, largely because of its aforementioned advantages, radiology remains a principal method of evaluating horses with joint disease.

The radiological features of OA mirror the pathological changes occurring in the affected joint (Figure 61-8).

TABLE 61-3

Synovial Fluid Cytology for Various Clinical Conditions and Diagnostic or Therapeutic Manipulations* 249-256									
PARAMETER	MILD			INFECTIOUS ARTHRITIS†	ARTHROCENTESIS‡	BALANCED		GENTAMICIN‡	DMSO‡ (10% SOLUTION)
	NORMAL	SYNOVITIS (e.g., OCD)	OSTEOARTHRITIS			ELECTROLYTE SOLUTION‡	LOCAL ANESTHETICS‡§		
Total leukocytes (per µL)	50-500	20-250	≤1 × 10 ³	20-200 × 10 ³	1-4 × 10 ³	6-45 × 10 ³ (typically 20 × 10 ³)	2-10 × 10 ³		8-40 × 10 ³
Neutrophils (%)	<10	<10	<15	>90 (variable toxic changes)	50	80	60	50	>50
Mononuclear cells (%)	>90	>90	>85	<10	50	20	40	50	<50
Total protein (g/dL)	0.8-2.5	0.8-3.0	0.8-3.5	4.0-8.0+	1.5-2.5	3.0-4.0	2.5-4.0	4.5-6.0	2.5-4.0

*Listed ranges are approximate. Considerable variability exists in published reports.
†Significant elevations in leukocyte counts and total protein concentration occur within the first 12 hours in experimentally inoculated joints. Values shown represent those observed at 24 hours.
‡Leukocyte counts and total protein concentrations correspond to the maximum values that typically occur within the first 24 hours.
§Synovial response to lidocaine and mepivacaine are comparable.

Fig. 61-8 • Dorsopalmar radiographic image of the metacarpophalangeal joint of a horse demonstrating radiological changes of advanced osteoarthritis. There is periarticular osteophytosis, joint-space thinning, and subchondral bone increased radiopacity (sclerosis) and radiolucency (lysis).

Initially, joint space narrowing, subchondral increased radiopacity (sclerosis), and osteophytosis occur. With time, subchondral radiolucent defects (lysis), osteochondral fragmentation, and eventually ankylosis may develop (Box 61-1). In horses substantial differences appear between specific joints respecting the relative degree of these changes. For example, radiologically evident changes tend to be less dramatic and appear later in the disease process in the metacarpophalangeal and metatarsophalangeal joints than in many other articulations.

Other Imaging Modalities

Increasingly available are other imaging modalities for assessing joint diseases. Among them are nuclear scintigraphy, MRI, and ultrasonography.

Nuclear Scintigraphy

Although more commonly used to detect nondisplaced, incomplete fractures and to identify stress-related bone damage in performance horses, nuclear scintigraphy can provide useful information in selected horses with OA (see Chapter 19). Whereas radiography (and related techniques, including computed tomography) provides considerable anatomical detail of osseous changes in affected joints, nuclear scintigraphy yields current physiological information on bone metabolism. The main disadvantages of scintigraphy are its relatively poor resolution (isotopes produce much fewer gamma rays than the number of x-rays generated by a cathode tube) and a lack of specificity because bone responds to most insults by increasing turnover. Owing to the unavailability of a cartilage-specific agent, the most common approach to the scintigraphic study of OA is using the delayed bone phase images, obtained 3 to 4 hours after injection of the radiopharmaceutical. Currently

BOX 61-1

Radiological Features of Osteoarthritis

Radiological Feature	Pathogenetic Mechanism*
Periarticular osteophytosis	Endochondral ossification occurring at bony margins of unknown cause. Possible repair attempt modulated by altered cytokine milieu.
(Asymmetrical) Joint space thinning	Cartilage degeneration and loss. [†] Usually at areas of weight bearing or high stress. May be absent when focal cartilage loss occurs.
Subchondral increased radiopacity	Deposition of new bone as a response to changes in force transmission and from healing of trabecular microfractures. Corresponds to areas of maximum stress. Clinically significant sclerosis often corresponds to full-thickness cartilage loss.
Subchondral radiolucency	Less common change of uncertain pathogenesis. Possibly pressure necrosis from synovial fluid gaining access to subchondral plate via fissures, or related to pressure necrosis from trauma to bone.
Osteochondral bodies	Disintegration of joint surfaces or fractured osteophytes. May represent inciting lesions (e.g., osteochondral fracture).
Advanced remodeling/ankylosis	Articular response to advanced degeneration. Environment more consistent with fracture than synovial joint.

*Specific pathophysiological mechanisms and reasons for disproportionate representation of changes among and between joints remain unclear.

[†]Seldom used as a marker of disease progression because of problems with technical aspects of radiographic positioning and focal-film distance.

used agents are the bisphosphonates, which bind to the microcrystals of hydroxyapatite in bone. Areas of increased bone modeling have enhanced localization of the radiopharmaceutical, as long as an adequate blood supply exists.

It has long been known that bone-seeking isotopes accumulate rapidly in the bone of OA joints.²⁶⁸ The most intense radiopharmaceutical uptake typically occurs in the subchondral bone and at the osteochondral junctions of osteophytes, although temporal variation in the anatomical distribution of uptake may occur, as was illustrated in an animal OA model.²⁶⁹ Evidence exists that scintigraphy is useful in predicting the progression of OA in the human knee,²⁷⁰ and scintigraphy apparently may prove useful in diagnosing preclinical joint disease, that is, before the appearance of radiological abnormalities.²⁷¹ Conversely, bone phase images may be normal in chronic OA joints if the rate of bone turnover returns to normal.

In the equine athlete, scintigraphy has proved useful to document a number of sport-specific lesions among different types of equine athletes.²⁷¹⁻²⁷³ Unlike the human digit, the size of the bones in the equine skeleton is sufficient that relatively precise anatomical localization of lesions is often possible. Moreover, nuclear scintigraphy has the advantage of allowing a survey of all joints in a single examination. Importantly, as for radiography, close correlation between lameness and scintigraphic findings does not always exist.^{271,274}

Magnetic Resonance Imaging

MRI involves detecting alternating electrical current produced when hydrogen protons, predominately found in fat

and water, are subjected to pulsed electromagnetic fields applied in a specific manner (see Chapter 21). The rate at which protons change orientation varies among soft tissues and fluids of different composition, which allows the considerable tissue discrimination possible with MRI.

MRI is assuming a growing role in assessing joint disease in people and has a number of compelling advantages over many of the existing imaging modalities. Specifically, MRI has the capacity to provide noninvasive, high-resolution, three-dimensional (tomographic) images of all joint components. Importantly, advances in equipment and improved imaging sequences allow direct evaluation of articular cartilage, rather than the indirect assessment obtained using conventional radiography. Specifically, high-field MRI can be used to evaluate cartilage morphology, determine tissue volume, and evaluate cartilage composition. In human patients, detailed analysis of cartilage structure, including the detection of subtle cartilage lesions, is now possible using current sequences and protocols.²⁷⁵ Cartilage loss is a hallmark of OA, and assessment of cartilage volume using MRI has been shown to be both sensitive and reliable.^{276,277} In the future, quantitative assessments of cartilage volume and composition may prove useful to monitor disease progression and therapeutic responses. Specialized techniques, including the use of contrast agents (e.g., gadopentetate dimeglumine), enable the assessment of glycosaminoglycan content in joint cartilage. To date, the technique of delayed gadolinium-enhanced MRI of cartilage has proved useful in monitoring the influence of exercise on cartilage health and for assessing the effects of a number of interventions on matrix composition.²⁷⁵ Optimizing MRI as a diagnostic and monitoring tool requires sophisticated (high-field) equipment and considerable experience for proper image acquisition and interpretation.

Developments in low-field magnets and motion correction software adaptable to the standing horse have made possible diagnostic MRI of the equine distal limb; however, these systems are unsuitable for evaluating cartilage in the manner described previously.²⁷⁸⁻²⁸⁰

To date, MRI studies of equine joints have been largely limited to anatomical and correlative studies of cadaver specimens.²⁸¹⁻²⁸⁴ In one of the few published reports of using the technique to investigate OA in the horse, post mortem magnetic resonance images of the metacarpophalangeal joint correlated well with arthroscopic and necropsy findings.²⁸⁵ Widespread use of MRI in horses is limited by the availability, expense, and the tunnel configuration of currently available equipment; however, it holds considerable promise as a diagnostic and monitoring tool in the future.

Ultrasonography

Ultrasonographic evaluation of diseased joints represents an additional diagnostic tool that has enjoyed increased use lately (see Chapter 17). Ultrasonography initially was used to assess chronic proliferative synovitis in the metacarpophalangeal joint.^{286,287} More recently its use has expanded to include most appendicular (and some axial) skeletal joints.

The principal benefit of ultrasonographic examination over conventional radiography is its superiority in demonstrating soft tissue abnormalities such as thickened synovial and capsular tissues and damaged intraarticular and periarticular ligaments. With experience and an appropriate knowledge of the regional anatomy and acoustic principles, it is also possible to identify and localize accumulations of synovial or other fluids. Although the ultrasound beam cannot penetrate the cortex, surface characteristics of bone can be evaluated, including periarticular osteophytes and enthesophytes, osteochondral fragments, and irregularities in the subchondral plate. Ultrasonographic features of arthritic cartilage include thinning, loss of sharp contours, and changes in echogenicity. Inherent limitations of ultrasonography preclude its use in areas where the tissue overlying the joint of interest is too voluminous and for structures having a shape or orientation that is not conducive to ultrasonographic evaluation. The basic principles and techniques of ultrasonographic examination of equine joints have been thoroughly reviewed.²⁸⁸

Chapter 62

Markers of Osteoarthritis: Implications for Early Diagnosis and Monitoring of the Pathological Course and Effects of Therapy

David D. Frisbie

Although joint disease can be diagnosed using routine clinical methods, more accurate and earlier diagnosis may

lead to identification of osteoarthritis (OA) before irreversible changes occur within joint tissues. Measuring levels of molecular products of tissue turnover, known as biomarkers, from healthy and diseased cartilage and bone has the potential to achieve early diagnosis and allow a better understanding of the pathophysiology of OA. The potential also exists to monitor disease, especially in response to novel therapeutic agents. Work with biomarkers of articular cartilage and bone in people and horses with OA has yielded promising results. This chapter discusses some of the markers that currently are being evaluated in synovial fluid and serum samples, with a focus on those of potential benefit to the equine industry.

STRUCTURE AND METABOLISM OF ARTICULAR CARTILAGE AND BONE IN HEALTH AND DISEASE

Articular cartilage is a complex tissue with an extensive extracellular matrix. The two main components that define the cartilage matrix are type II collagen and aggrecan (see

Chapter 61). A balance of synthesis and degradation orchestrated by the chondrocytes maintains normal populations of these molecules within the cartilage matrix. Osteocytes, osteoblasts, and osteoclasts maintain the structural and functional integrity of bone matrix by regulating synthetic and degradative pathways. Synoviocytes also influence homeostasis in cartilage and bone. OA often is characterized by degradative changes within articular cartilage, bone, and synovium. Direct and indirect factors assault the matrix molecules of these tissues, resulting in degeneration and loss of some macromolecules.

What are direct and indirect molecular markers? Direct molecular markers specifically identify a known molecular process within a given tissue. For example, fibrillar collagens, such as types I and II, are synthesized as immature procollagens that undergo proteolytic changes before conversion to mature collagen fibrils. Peptides at either end of the procollagen molecule are cleaved before the procollagen is incorporated into a mature collagen fibril. Estimations of type II collagen synthesis were obtained from synovial fluid and serum samples by using a specific antibody that recognizes the propeptides cleaved from the carboxyl termini.¹ Conversely, an indirect molecular marker reflects more general change that is not clearly definable and may represent contributions from several events and tissues. Indirect markers are cytokines, growth factors, and matrix metalloproteinases (MMPs). OA involves changes in subchondral bone and synovium; therefore assessment of molecular markers from these tissues is relevant.

INDIVIDUAL SKELETAL BIOMARKERS OF ARTICULAR CARTILAGE METABOLISM IN OSTEOARTHRITIS

Anabolic Processes

The carboxyl propeptide of type II collagen is a useful measure of the anabolic process of type II collagen synthesis. Studies have shown that levels of carboxyl propeptide of type II collagen were significantly higher in synovial fluid from people with OA compared with those without OA. Levels peaked early in the radiological progression of the disease and declined in patients with severe radiological changes.^{2,3} This biomarker also has been shown to change significantly in serum samples from people with OA and rheumatoid arthritis.^{4,5}

Chondroitin sulfate (CS) is a major glycosaminoglycan (GAG) of aggrecan, and measuring specific CS epitopes on newly synthesized proteoglycan (PG) molecules is a useful biomarker for aggrecan synthesis. An epitope called CS-846 that normally is found in fetal tissues, but is almost absent in healthy adult articular cartilage, has been measured in many species. Levels of CS-846 epitope were increased in synovial fluid in people after injury or primary OA compared with levels in synovial fluid from normal joints. Serum levels were elevated in joint disease but to a lesser extent than synovial fluid levels.^{6,7} Other CS epitopes such as 3B3 and 7D4 were shown to be useful in assessing cartilage injury in animal models and in people with clinical disease.⁸ Using arthroscopic evaluation, a negative correlation was found between synovial fluid 3B3 concentrations and gross articular damage that was thought to be caused

by decreased normal cartilage volume, or inhibition of synthesis, with increasingly severe lesions. Conversely, in people, increased levels of synovial 7D4 epitope were found in diseased knees compared with contralateral normal knees.⁹

Catabolic Processes

Measuring the degradation of type II collagen is of potential benefit in monitoring OA. Antibodies have been developed to identify exposed but previously inaccessible cleaved or denatured type II collagen fragments. Significant elevations in levels of degraded type II collagen were demonstrated in synovial fluid and serum samples from horses, dogs, and rabbits with experimentally induced OA.^{10,11} Significant increases were detected in the serum of people with OA, with a correlation to disease activity.¹⁰

Keratan sulfate (KS), one of the GAGs found on proteoglycan molecules of aggrecan, has been evaluated extensively. In people, elevations in serum levels of KS were associated with OA in some, but not all, studies.^{7,12,13} Lack of correlation of serum¹⁴ and synovial fluid⁸ KS levels with cartilage damage compromises the value of serum KS as a biomarker of joint disease in people. In dogs, a specific KS epitope (5D4) was of limited value in experimentally induced and naturally occurring cruciate ligament injury.^{15,16} The usefulness of KS in serum and synovial fluid of horses with osteochondral fragmentation is also questionable.¹⁷

In an initial equine study of molecular markers, carboxyl propeptide of type II collagen and the GAG epitopes CS-846 and KS were measured in synovial fluid and serum of horses with and without carpal osteochondral fragments.¹⁷ Synovial fluid and serum CS-846 epitope concentrations were significantly higher in joints with osteochondral fragments compared with normal joints and showed good correlation with grades of cartilage damage. Serum concentrations of carboxyl propeptide of type II collagen were elevated in horses with osteochondral fragments, and good correlation between carboxyl propeptide of type II collagen concentration and arthroscopic lesion grade was found. A single blood sample assayed for CS-846 and carboxyl propeptide of type II collagen levels resulted in 79% accuracy for prediction of an osteochondral fragment.

CS-846, KS, and carboxyl propeptide of type II collagen concentrations were measured in synovial fluid of horses with normal joints and those with osteochondrosis.¹⁸ Significantly higher levels of carboxyl propeptide of type II collagen and lower amounts of CS-846 and KS epitopes were found in affected joints compared with normal joints.

Cartilage oligomeric protein (COMP) is an abundant noncollagenous protein constituent of cartilage. COMP was once thought to be cartilage specific, but it has also been localized in tendons and synovium. Serum and synovial fluid concentrations of COMP are increased in people with OA.^{19,20} A positive correlation exists between COMP levels and radiological grading of OA, progression of radiological changes,²¹ and results of nuclear scintigraphy in people.²² Gene expression of COMP in synoviocytes is up-regulated in OA, suggesting that this marker may be useful to indicate synovitis.

Unlike the elevation of COMP levels in people with OA, in horses initial studies demonstrated that serum and synovial fluid levels of COMP were significantly *lower* in horses

with diseased joints.²³ It appears that this discrepancy was caused by the antibody used in the initial equine studies recognizing mainly intact rather than intact and breakdown products of COMP. Thus a subsequent study²⁴ in the horse using an antibody (14G4) recognizing both intact and breakdown fragments confirmed that COMP levels increase with OA.

INDIVIDUAL SKELETAL BIOMARKERS OF BONE METABOLISM IN JOINT DISEASE

Anabolic and catabolic cascades exist in bone, but specific markers in normal and disease states are not clearly defined. This section deals only with bone markers thought to be important in joint disease.

Anabolic Processes

Osteocalcin (OCa) is a small noncollagenous protein associated with bone assembly and turnover and has been measured in serum and synovial fluid samples from people with OA. Levels of OCa correlated with bone scan findings and markers of cartilage metabolism.^{22,25} However, because OCa levels are higher in serum than synovial fluid, OCa in synovial fluid may be derived from peripheral blood and may not reflect local joint disease.²⁵

OCa levels were measured in horses, and, as in people, they appear to vary with age and with the administration of corticosteroids,^{25,26} but the effect of gender remains unclear.²⁶ General anesthesia affects serum OCa levels for 4 days.²⁷

Bone-specific alkaline phosphatase is an isoform of alkaline phosphatase that is expressed at high levels on the cell surface of the bone-forming osteoblasts and plays an important role in bone formation. In a recent equine study, a correlation was found between synovial fluid levels of bone-specific alkaline phosphatase (BAP), KS-5D4 epitope, and total GAG, as well as between all three biomarkers, and the amount of joint damage defined arthroscopically.²⁸ This supports a putative role for altered subchondral bone metabolism in equine OA.

Catabolic Processes

Type I collagen C-telopeptides (CTX) may be useful markers of bone resorption. CTX levels in people with rheumatoid arthritis were positively correlated with indices of disease activity and joint destruction.^{29,30} The marker was influenced by the administration of corticosteroids. CTX is present in equine serum, although its usefulness as a marker of pathological processes is unknown.³¹

Human bone sialoprotein is found only in adult bone, and levels are seven times higher at the interface of cartilage and bone compared with other locations in bone.³² Serum levels are elevated significantly in people with clinically apparent OA and those with bone scans consistent with OA.^{32,33} Equine bone sialoprotein has yet to be characterized, but development of an assay is currently underway. The hope is that this will be useful in identifying subchondral bone damage in horses with OA.

FUTURE OF BIOMARKERS IN OSTEOARTHRITIS

Limited data are available regarding the use of biomarkers to diagnose and monitor equine joint disease. Factors

influencing levels of biomarkers include liver and kidney clearance, circadian rhythms, intestinal peristalsis, exercise level, age, breed, diet, sex, drug administration, surgery, and general anesthesia. Methods of sample collection and storage also may be influential.

Although biomarkers may have a role in diagnosis and monitoring equine OA, a combination of markers likely will be required, especially because so many factors influence activity. Proof-of-principle work has been completed showing that biomarkers significantly change in the face of experimentally induced OA, and this change is significantly greater than with exercise alone.^{34,35} Specifically, synovial fluid concentration for eight of eight biomarkers was significantly increased in OA-affected joints of horses undergoing exercise compared with sham joints of similarly exercised horses. Likewise, serum from OA-affected horses had a significant increase in six of eight biomarkers compared with serum from similarly exercised horses. Using biomarker levels from either synovial fluid or serum, horses could be correctly categorized into the appropriate group (OA-affected or sham) 100% of the time within 14 days of OA induction using discriminant analysis, suggesting great promise for the use of biomarkers.

To date, in a clinical setting, several cross-sectional studies have looked at numerous biomarkers in both synovial fluid and serum for the potential to be useful in noninvasive prediction of disease severity. Specifically, COMP was significantly altered in serum in horses with clinical OA compared with control horses.³⁶ Differences in synovial fluid COMP levels were identified when making similar comparisons in horses with OA.^{24,37,38} Another cross-sectional study³⁹ using the contralateral limb as a control demonstrated that concentrations of BAP, KS, KS/GAG ratio, and hyaluronan were all significantly different in early OA compared with contralateral joints. It was also observed that BAP and KS concentrations and the KS/GAG ratio had good correlations with articular cartilage pathology. These cross-sectional studies provide good examples for the potential use of biomarkers in equine medicine; prospective longitudinal studies are the next step for providing further proof of principle.

One such study has been completed through collaboration of the Equine Research Center at Colorado State University and equine veterinarians practicing at southern California Thoroughbred racetracks. Two- and 3-year-old racehorses were entered in the study (N = 238).⁴⁰ Horses had monthly musculoskeletal examinations, and blood was collected and stored for later biomarker examination. Horses were followed for a maximum of 10 months and were considered to have sustained an injury if they were out of training for more than 30 days. Horses with solitary musculoskeletal injuries and completion of more than 2 months in the study were analyzed for biomarker levels, along with a randomly selected control population of uninjured horses. The following were considered musculoskeletal injuries: intraarticular fragmentation, tendon or ligamentous injury, stress fractures, and dorsal metacarpal disease. Fifty-nine horses sustained a single musculoskeletal injury; 71 acted as uninjured controls. The greatest change in biomarker levels was 4 to 6 months before injury. Using sophisticated statistical modeling, it was possible, based on biomarker levels in this group of horses, to

accurately predict horses that would sustain an injury 73.9% of the time. Given these promising results, another study has been instituted in Western performance horses, which have a less tightly controlled training pattern

compared with Thoroughbred racehorses. Because exercise is known to affect biomarker levels, this will be an important test of the “real world” application of biomarkers in musculoskeletal disease.

Chapter 63

Gene Therapy

C. Wayne McIlwraith and David D. Frisbie

It was well stated by Anderson in *Nature* in 1998: “Despite our present lack of knowledge, gene therapy will almost certainly revolutionize the practice of medicine over the next 25 years.”¹ Gene therapy has the potential to revolutionize intraarticular therapy, both for the prevention of osteoarthritis (OA) and its management.

There are two approaches to gene therapy: (1) identifying a genetic disease (e.g., OA) and then replacing the defective gene, or (2) using gene therapy to increase levels of selected therapeutic proteins, as with interleukin-1 receptor antagonist (IL-1ra). Until gene defects are clearly identified, gene therapy for OA is likely to use the second approach, promoting production of disease-modifying agents such as catabolic antagonists or anabolic promoters.

REVIEW OF COMPONENTS OF GENE THERAPY

A gene, which is a functional unit of DNA, consists of a DNA sequence that produces a single polypeptide. This gene sequence codes for a specific messenger RNA that goes from nucleus to cytoplasm to translate the amino acid sequence (protein).

Gene therapy is targeted on the production of a selected therapeutic protein to alter a disease process. This protein may enhance (e.g., insulin-like growth factor-1 [IGF-1]) or repress (e.g., IL-1ra) a specific cellular process. The essential components of gene therapy include (1) isolation of a gene (called cloning), (2) manipulation of the gene (engineering), and (3) transfer of the gene into the host cells (transfection/transduction). The gene sequence is initially isolated and characterized and is then engineered by the addition of regulatory elements (promoters) that allow control of protein production.

The essential component of gene transfer is the vector. Gene delivery vectors facilitate the transfer of the therapeutic gene into the nucleus of the target cell. Once in the nucleus, the gene is decoded (expressed) to produce a protein. Viruses, the most commonly used vectors, have the ability to transfer genes into a host cell in an efficient, logical, and easy manner. Viruses used as vectors have been rendered incapable of replicative spread by removal of viral genes and insertion of the therapeutic gene(s). Viral vectors are more efficient than nonviral vectors.

There are two potential methods of gene transfer. Ex vivo gene transfer is an indirect technique where the cells

are collected from the joint and grown in the laboratory (e.g., synovial cells). The gene is then transferred (transduced) into cultured cells using a viral vector, and the transduced cells are reimplanted after testing for protein production. Ex vivo transfer is safer but less convenient than the second technique, in vivo transfer. In vivo transfer involves direct transfer of a vector to the target tissues. For example, synovial cells could be transfected by direct transmission of an *IL-1ra* gene using an adenovirus vector injected into a joint (Figure 63-1). Adenoviruses are the most common vectors proposed for use in human patients with clinical disease² and were used in our equine studies.³⁻⁹ Adenoviral vectors can transduce dividing and nondividing cells and are amenable to in vivo transfer. The adenoviral vector takes up an episomal location (extrachromosomal) in the host nucleus. Second-generation vectors give protein expression for 21 to 40 days.

GENE THERAPY AND JOINT DISEASE

Our investigation of the potential value of gene therapy in the treatment of OA is partially based on limitations of traditional therapy. Currently, most therapeutic agents need to be directly administered intraarticularly, and the half-life of most commonly used agents is short.^{10,11} Gene transfer provides an excellent alternative to conventional therapy because a single intraarticular injection results in the production of the specific therapeutic protein within diseased joint(s) for a prolonged period.¹² The potential for the use of gene therapy is best illustrated by our work

Fig. 63-1 • Schematic drawing representing in vivo gene transfer to the synovium. This is the way in which gene therapy with interleukin-1 receptor antagonist was performed. (Reproduced with permission from McIlwraith CW: Milne lecture: from arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:83, 2005.)

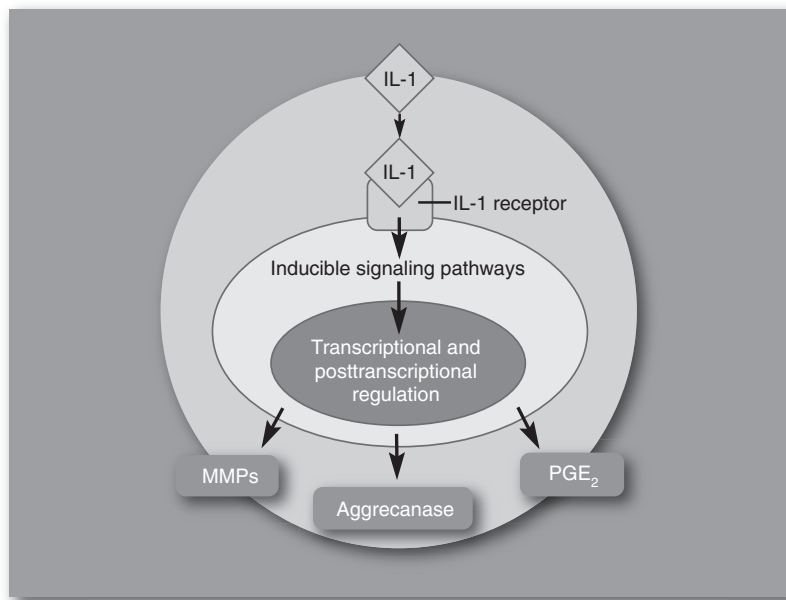

Fig. 63-2 • Diagram of interleukin-1 (IL-1) activation of matrix metalloproteinase, aggrecanase, and prostaglandin E₂ release acting through IL-1 receptors on the cell membranes. (Reproduced with permission from McIlwraith CW: Milne lecture: From arthroscopy to gene therapy—30 years of looking in joints, *Proc Am Assoc Equine Pract* 51:73, 2005.)

demonstrating that experimental OA can be suppressed by the use of gene therapy. Cytokines such as interleukin-1 (IL-1) and tumor necrosis factor (TNF) modulate the synthesis of metalloproteinases (MMPs) by synovial cells and are largely responsible for the mediation of joint disease.¹³⁻¹⁵ The mechanism by which IL-1 causes up-regulation of deleterious mediators is illustrated in Figure 63-2.

Any of the articular tissues, including synovium, articular cartilage, and meniscus, are possible targets for gene transfer. However, the synovium is the best because of its large surface area and contact with the joint space, and has been used with IL-1ra. Synovium is also a convenient target because the gene vector can be administered intraarticularly. Extracellular matrix would limit vector penetration in cartilage cells.

USE OF GENE THERAPY TO PREVENT ARTICULAR CARTILAGE DEGRADATION IN OSTEOARTHRITIS

It is now well accepted that the IL-1 “system” is important in the pathogenesis of OA and articular cartilage degradation. There are two agonists, IL-1 α and IL-1 β , with IL-1-converting enzyme responsible for activation of both cytokines. There is also an IL-1ra. Both the agonists and the antagonists function through type I and type II receptors on the cell membrane of the target cell (this can be synovium or a chondrocyte) (see Figure 63-2). Up-regulators of IL-1 gene transcription include IL-1 itself, TNF, and IL-2. IL-1 in turn up-regulates MMP activity, prostaglandin E₂, and IL-6, which are important in articular cartilage matrix degradation. The type I IL-1 receptor mediates biological responses to IL-6. The type II receptor does not deliver biological signals but tracks IL-1 and inhibits its action. Type II soluble receptors are also potential therapeutic agents. Following intraarticular administration of IL-1ra protein in the Ponn-Nuki model of OA, there was a dose-dependent reduction

in the incidence of osteophytes, size and grade of tibial cartilage erosion, cartilage histological changes, and MMP-1 expression.¹⁶ However, multiple and regular dosing of the protein is essential.

The first report of gene transfer of IL-1ra was in 1993.¹⁷ A collaborative effort between the University of Pittsburgh School of Medicine Department of Orthopedic Surgery and Molecular Genetics and Colorado State University (CSU) Orthopaedic Research Center was successful in treating experimental equine OA using gene therapy with equine IL-1ra using an adenoviral vector. Our collaborators Evans and Robbins had previously done work in experimental animals using an adenoviral vector to transport the equine *IL-1ra* gene, and it was this adenoviral vector containing the equine gene that was used in our studies. The first step was the identification and sequencing of the gene and coding equine *IL-1ra*, previously done in our laboratory in 1998.¹⁸

Proof-of-principle experiments began. First, in vitro expression of an active equine IL-1ra protein after gene transfer of the equine *IL-1ra* gene sequence to cultured equine synoviocytes using an adenoviral vector was validated.¹⁹ Synoviocytes were transfected with Ad-EqIL-1ra at 0, 1, 10, and 100 multiplicity of infection. We assayed the media for and found sufficient active protein (Quantikine human IL-1ra immunoassay; R&D Systems, Minneapolis, Minnesota, United States). Then in an in vivo dose titration study we found that our Ad-EqIL-1ra vector led to a dose-dependent increase in the concentration of IL-1ra in synovial fluid. The maximum duration of IL-1ra production (35 days) was with 10 or 20 $\times 10^{10}$ particles per joint. However, a higher dose of 50 $\times 10^{10}$ produced an undesired synovial leukocytosis.

Next we tested this regimen using our previously described equine OA model^{20,21} using eight treated and eight control horses.⁴ Fourteen days after surgery, horses received 20 $\times 10^{10}$ Ad-EqIL-1ra viral particles per joint and

continued in a standardized exercise protocol. Relevant levels of IL-1ra protein were measured in the synovial fluid. At 8 weeks, treated horses showed marked reduction in full-thickness cartilage erosions in the induced OA joints and lower inflammatory scores in the synovium compared with control horses. Safranin O fast green staining was depleted in the control joints but was close to normal in the treated joints. There was increased proteoglycan synthesis in the articular cartilage of treated joints. From these data we concluded that transduction of cells with Ad-EqIL-1ra led to synthesis of biologically active equine IL-1ra and excellent suppression of experimentally induced equine OA.

To put the therapeutic benefit of this gene therapy into perspective compared with conventionally used medication, gene therapy was better at reducing the progression of experimentally created OA than were triamcinolone acetonide (Vetalog; Fort Dodge Animal Health, Overland Park, Kansas, United States)²⁰ and methylprednisolone acetate (Depo-Medrol; Pfizer, New York, New York, United States),²¹ both of which were tested in similar fashion. This was the first study to demonstrate both clinical improvement as a result of gene therapy and significant improvements in gross and histological changes. We concluded that we may have discovered a practical and potentially effective therapy for equine OA. However, subsequent studies revealed that repeated administration of the viral vector induced substantial reactive synovitis, and now our focus has been in trying to achieve a better, nonreactive vector. Work is centered on attempts at developing an adeno-associated viral (aaV) vector, which has been difficult and frustrating. However, recent work in our laboratory has shown good green fluorescent protein expression with an equine aaV vector, and we are optimistic that we have found a better method of gene therapy with IL-1ra in the horse.^{22,23}

GENE THERAPY AND PROMOTION OF CARTILAGE HEALING

There is potential value in using anabolic genes, such as IGF-1, to heal existing cartilage defects. Adenoviral-mediated

IGF-1 gene transduction of equine synovium caused persistent elevations of synovial fluid IGF-1 ligand.²⁴ Enhancement of cartilage healing in an equine model was demonstrated with genetic modification of chondrocytes with IGF-1.²⁵

Following our positive results with *IL-1ra* gene transfer in experimentally induced OA, the possibility of gene therapy with both IL-1ra and IGF-1 was explored. We reasoned that promotion of anabolism in combination with inhibition of catabolism could provide an appropriate environment for articular cartilage healing. In another collaborative effort among our laboratory, Cornell University, University of Pittsburgh, and Harvard, we have evaluated the value of the combined gene therapy protocol using IL-1ra to decrease the effect of IL-1 on cartilage repair and IGF-1, which had previously been shown to enhance cartilage healing and to reduce the deleterious effects of IL-1.²⁶⁻²⁸ Using an osteoarthritic IL-1 coculture (synovium and articular cartilage), gene transduction with IGF-1 and IL-1ra proteins was demonstrated using an adenoviral vector with the reduction of proteoglycan loss from the cartilage.²⁶ There was also restoration of cartilage matrix without IL-1 being detected using the same *in vitro* system.²⁷ Combination gene therapy was then evaluated *in vivo* using full-thickness articular chondral defects treated with microfracture in the horse.²⁸ Gene therapy enhanced the quality of the repair tissue in full-thickness equine chondral defects compared with microfracture alone, resulting in increased concentration of type II collagen and aggrecan in the repair tissue.

GENE THERAPY AND BONE HEALING

The delivery of growth factors using gene therapy to enhance bone healing was reviewed.²⁹ Initial work at CSU was done evaluating an adenoviral-bone morphogenetic protein-2 (BMP-2) gene therapy protocol in an infected nonunion fracture model.³⁰ Beneficial effects were obtained, and more recently the use of adeno-BMP-2 gene therapy is being evaluated in a splint gap osteotomy model in the horse.

Chapter 64

Models of Equine Joint Disease

Chris E. Kawcak

Animals have been used extensively as models of joint disease to study clinical conditions in people. However, veterinary researchers have the luxury of using experimental animals from species that are clinically relevant. Unlike in human research, one has no need to assume similarity in findings between species. Equine models of joint disease

have been used for several decades to test the effects of drugs and various treatments on joints and to evaluate the pathogenesis of certain diseases. Joint disease can be assessed in horses with clinical disease; however, large numbers are needed for each treatment group to see significant statistical differences in the face of great variation among individual horses. Owner compliance, differing treatment protocols among clinicians, and variability among horses in response to disease and treatment, as well as conformation, limb use, and size, all contribute to this variation. Furthermore, clinical studies take a long time to perform, and the effects of treatment take a long time to be seen. Consequently, *in vitro* and *in vivo* models have been developed to give researchers better-controlled studies that can be done in a relatively short time.

The model to be used should be designed to answer a question by using a testable hypothesis. Variability should

be reduced as much as possible so that the question can be answered with little outside influence. However, as more and more variables are eliminated, the model becomes less representative of the clinical situation. For instance, the efficacy of oral joint supplements in reducing joint disease cannot rely solely on results from *in vitro* studies. The drugs must be tested *in vivo* to determine if and how they work. However, to determine the effects of a drug or chemical on articular cartilage matrix metabolism, a quick, relatively inexpensive *in vitro* test can be conducted. Therefore the type of model to be used depends on the question to be answered.

Two types of models are used to study equine joint disease. *In vitro* models can be used to study various treatments, using cells, cell lines, or tissues harvested from joints to test usually one specific pathological pathway or treatment scheme. *In vivo* systems can be used to test drugs and to determine the pathophysiological response to an insult. Unlike *in vitro* studies, *in vivo* studies involve the entire joint, allowing researchers to assess the whole organ to determine truly the clinical efficacy of a drug.

In this chapter the complexity of joint disease and the use of joint models are discussed. The difficulties in modeling joint disease, the rationale for selecting specific models, specific examples of models used for the study of the joint disease, and the current status and future use of equine models of joint disease are considered.

COMPLEXITY OF JOINT DISEASE

The joint can be considered an organ because it is composed of several different types of tissues that biomechanically and biochemically interact with each other. Joint disease can result from several factors. First, the disease has a direct biochemical effect on all tissues. For instance, with synovitis, inflammatory mediators can be released into the joint space and put the articular cartilage into a catabolic state.¹⁻⁴ Second, the pain produced by joint disease can result in a change in the character of the gait.^{5,6} Consequently this change in joint loading alters biomechanical inputs on all tissues, resulting in a biochemical change in the response by tissues.^{7,8} Third, disease of one tissue can result in a change in the mechanical input on another tissue. For instance, articular cartilage degeneration, which can result in increased stress to subchondral bone, can induce a sclerotic response.⁹ As another example, subchondral bone sclerosis, which commonly occurs in racehorses, can lead to increased stress on overlying articular cartilage.¹⁰ Therefore in the live horse all tissues are affected by one another.

Because several factors can influence joint disease, researchers have attempted to control these influences in experimental studies. However, not all of the factors can be controlled. For instance, several mechanical factors play a role in joint disease; specifically, mechanical input can vary with horse size, exercise intensity, conformation, neurological control, and lameness. Consequently, differences in the stress to joints can result in changes in biochemical pathways in those tissues. For instance, ponies are one third to one half the size of horses and have little naturally occurring joint disease. Therefore they may not be the best equine models of joint disease for joint healing studies and exercise studies because of lower imposed stresses. However,

they are still good models if imposed stresses do not play a role in the specific disease being studied, such as induced synovitis models. Tissue material properties also have an influence on joint disease. For instance, weaker tissues undergo greater biomechanical changes than those that are stronger. Factors that control material properties of tissues include genetics, loading history, and age of the animal. The tissue remodeling status and the ability of horses to remodel articular cartilage, subchondral bone, and soft tissues can also influence joint disease, which is also affected by age, loading history, and genetics. The inflammatory response can also change the joint environment. Specifically, differences in the immune system at the time of disease can greatly influence the inflammatory response to the joint and influence the concentration of cytokines released into the joint.

Variables such as age, size, conformation, and neurological status can be controlled in experimental *in vivo* studies. However, loading history and the presence of subclinical disease are virtually impossible to control. With the advent of more sophisticated imaging equipment, such as computed tomography (CT) and magnetic resonance imaging (MRI), more information on loading history and subclinical disease can be obtained. For instance, subchondral bone density is indicative of loading history.¹¹ Therefore researchers at the Equine Orthopaedic Research Center (EORC) at Colorado State University often perform prestudy CT examinations to determine subchondral bone density as an indicator of loading history. Another benefit of CT and MRI is that some subclinical diseases may be more easily detectable. Researchers at the EORC also initiate a controlled exercise program on a high-speed treadmill before starting the study. The hope is that this can normalize the loading histories of experimental horses. Equally important as loading history and subclinical disease is the biomechanical and biochemical status of the articular cartilage, which at this time is difficult to assess noninvasively at the beginning of a project. With the advent of MRI and pressure probes, articular cartilage and bone matrix structure can be assessed more readily.

TYPES OF MODELS

In Vitro Models

Several types of models have been used to study joint disease. *In vitro* models have been used and are increasing in use for several reasons. Researchers in university settings are constantly driven to develop *in vitro* studies to reduce the use of live animals and to address the humane issues that surround live animal research. Currently, *in vivo* models are essential for testing new drugs. However, animal care and use committees at universities critically evaluate *in vivo* research projects to be sure that they are necessary. These committees are under constant pressure to ensure that research animal use falls within appropriate ethical guidelines. *In vitro* systems for studying joint disease can be performed on cells from the tissues of joints. Culture systems can be created for cells such as synoviocytes and chondrocytes in two-dimensional and three-dimensional matrices. Isolated cells also can be evaluated, within the individual matrices, or within artificial matrices. Isolated cells are used to evaluate cellular response to therapeutic agents. Specific outcomes are analyzed to determine cell

metabolism and proliferation. Some cell cultures are allowed or stimulated to produce the matrix, and specific cell matrix interaction and matrix metabolism can be studied. Cells are often cultured within artificial matrices to evaluate cell-matrix interactions and cell proliferation within the matrix.

Tissues from living systems are also used for *in vitro* study of joint diseases. The advantages of such a system over isolated cells are that cells can be maintained within the natural matrix and the experiments are relatively easy to perform. However, tissues must equilibrate in the culture medium to a steady state. This metabolic state may not truly reflect the *in vivo* state, because no axial load exists and the tissue edges are unconfined. The change in stress patterns and bathing in artificial media then influence articular cartilage matrix metabolism, often leading to increased articular cartilage matrix degradation. Tissues that are harvested from cadavers and specimens are placed within the medium, which is changed every 24 to 48 hours. These tissues then can be manipulated for study, and the medium and tissue can be evaluated. Media collected during the study can be analyzed for release or degradation of matrix components and inflammatory mediators. Tissues can be assessed for changes in cell proliferation, matrix synthesis, and characteristics of matrix degradation. Various molecular techniques can also be performed on the tissues.

Two types of tissue cultures are available. Single tissues can be studied to determine biochemical, molecular, mechanical, and histological changes that occur with certain influences.^{12,13} However, coculture systems also can be evaluated to determine interactions between tissues. Investigators in the EORC have studied synovium-articular cartilage and articular cartilage-subchondral bone coculture systems. Exposure of articular cartilage matrix to subchondral bone caused a significant reduction in articular cartilage matrix metabolism.¹⁴ Furthermore, similar findings also were seen in the synovium-articular cartilage coculture systems, in that exposure of articular cartilage matrix to subintimal tissues and vessels led to a significant reduction in articular cartilage matrix metabolism.¹⁵ From these studies one can conclude that exposure of various depths of synovium and subchondral bone to articular cartilage can lead to release of mediators that can change articular cartilage metabolism. Unlike the equilibration period for *in vitro* experiments, this change in metabolism is severe and long lasting. However, when articular cartilage is cocultured with synoviocytes, there is a protective effect on articular cartilage degradation. Therefore one can conclude that cocultured systems using pure cells can be used to measure simultaneous effects from both tissues.¹⁶

Examples of *in vitro* studies that have been performed on tissues and cells include study of enrofloxacin on articular cartilage explants,¹⁷ glucosamine and chondroitin on explants,^{18,19} glucosamine alone on cells,^{20,21} the effect of single-impact injury on articular cartilage explants,²² the effects of nonsteroidal antiinflammatory drugs and herbal preparations on tissues,²³ and evaluation of corticosteroids and growth factors on articular cartilage.²⁴ These studies demonstrate the robustness of *in vitro* systems to study various medications and pathological events.

In addition to study of specific tissues and cells, the isolated joints can be used to study various factors. For instance, Hardy and colleagues developed an isolated

perfused limb to study the physiological response of inflammation on joints.^{25,26} In addition, Bragdon and colleagues used the same system to evaluate drug delivery.²⁷ This system is shown to work well to study the physiological response of the joint to various factors. This is mostly focused on the vascular and cell permeability response. In addition, cadaver limbs can also be used to study various physical responses of joints and limbs. Easton and I used an isolated forelimb to study loading patterns and the correlation of subchondral bone density in the fetlock joint of horses.²⁸ Briefly, the isolated forelimb was placed in a loading system and the preparation was loaded to variable fetlock joint angles, including that corresponding to galloping. Dye staining was then used to characterize the loading pattern in the third metacarpal bone, the proximal sesamoid bones, and the proximal phalanx. It has long been established that fractures can be studied with this type of system, as illustrated by distal radial fracture repair.²⁹

In vitro experiments are relatively straightforward to perform and allow large numbers of repeats. Consequently the numbers are strong for statistical analysis. However, only one small portion of the disease process usually can be evaluated. Furthermore, the more tissues are removed from the natural joint environment, the greater the change in matrix metabolism and response to treatment.

In Vivo Studies

In vivo studies have been used for decades to study equine joint disease. The advantages of *in vivo* systems are that the cells and matrices are kept within the native environment and can be studied without the influence of harvest and culturing, and normal interaction among tissues can be maintained. The disadvantages are that live animals are humanely destroyed, and the costs can be prohibitive. *In vivo* studies are used for evaluating medications and articular cartilage healing techniques and for determining pathological responses to disease. An understanding of the clinical disease and an appreciation for strict experimental design are needed to produce useful *in vivo* models. *In vivo* studies in the horse have gained popularity because Frisbie and colleagues showed that equine articular cartilage is more similar to human cartilage than is cartilage from other species.³⁰

Various inciting mechanisms can be used to induce experimental joint disease. For instance, synovitis models are used to evaluate the sequence of events that occurs and the influence of various drugs and medications. Change in gait, measurement of inflammatory mediators, assessment of articular cartilage matrix metabolism, and various clinical tests have been studied. Examples of these studies include injection of lipopolysaccharide,^{1,31} interleukin-1,²⁶ sodium monoiodoacetate,^{32,33} filipin,^{2,34} polyvinyl alcohol foam particles,³⁵ carrageenan,³⁶ Freund's adjuvant,³⁷ blood,³⁸ and amphotericin⁶ into joints. Of these models, those that use the natural inflammatory mediators, such as lipopolysaccharide and interleukin-1, seem to be the best for promoting the natural cycle of events in inflammation. The advantages of such studies are that they are quick, relatively well investigated, and replicate a common clinical problem.

Instability models also have been studied in horses. The purposes of these studies have been to determine the sequence of events that occurs within tissues because of

instability and to induce osteoarthritis (OA).^{15,25,39} Once OA has been induced, various treatments can be examined. An example of an instability model includes cutting the collateral and collateral sesamoidean ligaments in the metacarpophalangeal joints of horses.³⁹ Unlike in the dog, complete surgical transection of the cranial cruciate ligament in horses has not resulted in progressive OA.⁴⁰ Mild osteophyte formation occurred in these joints, but no progressive articular surface changes or lameness were appreciated. The results are unlike those in horses with naturally occurring cranial cruciate ligament damage, in which some horses are lame and substantial articular cartilage damage may result. Unlike synovitis models, instability models are relatively long term and represent an example of chronic, progressive disease.^{41,42}

Forced exercise can also lead to changes in joint environment. Examples include evaluation of osteochondral tissues in response to various levels of exercise. Significant changes have been found in articular cartilage matrix biochemical and biomechanical properties in exercised horses compared with horses not exercised.⁴³ Strenuous exercise led to significant increases in calcified cartilage thickness, significant decreases in articular cartilage mechanical properties, and significant increases in fibronectin at the sites of degradation.⁴³⁻⁴⁵ Treadmill exercise led to significant increase in clinical disease in the metacarpophalangeal joints of horses. This was detected grossly and using various imaging techniques.⁴⁶ Currently several studies are ongoing to evaluate the effects of exercise to determine the level of exercise most appropriate for protecting the tissues of the musculoskeletal system. At the EORC horses with experimentally induced OA are being compared with young normal horses that are exercised, in the hope of differentiating clinical and diagnostic test results in horses undergoing exercise-induced adaptation from those in horses with joint disease. There have been recent studies on the effects of exercise on foals, weanlings, and yearlings, to investigate whether early exercise will lead to stronger musculoskeletal tissues, with generally negative results.⁴⁷⁻⁵³

The osteochondral fragment model is a blend of *in vivo* models and involves inducing a clinically relevant disease (Editors' note: for racehorses, but not necessarily for other equine athletes) through creation of an osteochondral fragment and imposed exercise. Researchers at the EORC have used this model extensively, which induces progressive OA yet is benign enough to induce grade 1 to grade 3 lameness.⁵⁴ In addition, osteochondral fragments have been taken from the tarsocrural joint and implanted into the carpus and metacarpophalangeal joint to induce inflammation.⁵⁵

Using the osteochondral fragment model various medications have been studied, including betamethasone,⁵⁶ intravenous hyaluronan,⁵⁷ triamcinolone acetonide,⁵⁸ and methylprednisolone acetate,⁵⁹ as have gene therapy for joint disease,⁶⁰ change of biomarkers with exercise,⁶¹ and the effects of exercise on imaging outcomes.⁶² The response to avocado and soybean unsaponifiables,⁶³ intraarticular autologous conditioned serum,⁶⁴ and the interleukin-1 receptor antagonist gene⁶⁵ have also been evaluated. Mechanical nociceptive thresholds have been determined.⁶⁶

Models of disuse also have been shown to induce osteochondral damage. Disuse is a clinically relevant problem that induces articular cartilage and subchondral bone atrophy. Examples include a significant reduction in

articular cartilage matrix metabolism in horses with a lower limb cast.⁶⁷ Furthermore, application of a cast for 7 weeks, followed by treadmill exercise, has been shown to lead to a significant increase in lameness in the limb with the cast and a significant decrease in bone formation.⁶⁸⁻⁷⁰ Disuse models are important, because casts are used clinically and can lead to substantial problems after removal. Often the race is between healing and the degradative changes caused by disuse.

Models of articular cartilage healing have been studied extensively because of the need to test various modes of treatment *in vivo*. These models also have been stimulated by the cutting edge research being done by several equine research laboratories around the world and the fact that the horse is becoming more accepted as a model of articular cartilage healing for people. If an implant or technique can stimulate and maintain articular cartilage healing in a horse, then the thought is that the implant or technique should work in people. Several equine models are used to study joint healing. Besides the type of treatment that is tested, the models vary in the depth and size of articular cartilage defect formation. Partial-thickness and full-thickness articular cartilage, articular and calcified cartilage, and osteochondral defects have been evaluated *in vivo* and treated with various techniques.

The size and location of osteochondral lesions appear to have an effect on healing.⁷¹ Small lesions in weight-bearing areas healed better than large lesions and lesions in non-weight-bearing areas. The physical characteristics of the lesions also affect healing. For instance, subchondral cystic lesions developed in horses with linear articular cartilage lesions but not in horses with elliptical lesions.⁷² The subchondral defects did not fill in with bone. Trauma to the subchondral bone led to cyst formation.⁷³ The presence or absence of calcified cartilage also plays a role in articular cartilage healing. Calcified articular cartilage has reduced defect filling compared with defects without the presence of calcified cartilage.⁷⁴ However, the conclusion from that study and others was that calcified cartilage may provide support for improved healing. Consequently the influence of calcified cartilage on healing is currently being investigated.⁷⁵

Various articular cartilage resurfacing treatments have been tested *in vivo*, including periosteal grafts,^{76,77} sternal cartilage grafts,^{78,79} mosaicplasty,⁸⁰ subchondral micropicking,⁷⁴ and cell-based grafting.⁷⁷ Sternal cartilage grafts have produced short-term benefits; however, significant degradation occurred after 4 months, with subchondral cyst formation.^{78,79} Mosaicplasty has shown promise; however, harvest sites are needed to obtain tissue for implantation.^{80,81} Subchondral bone micropicking may improve healing of osteochondral defects and is simple to perform.⁷⁴ Cell-based grafting may be beneficial, but it requires special equipment and advanced training to perform.^{82,83} Other techniques that have been assessed in the horse include radiofrequency and mechanical debridement^{84,85}; various growth factors in gene therapy^{86,87}; and stem cell therapy.⁸⁸ The horse may be an ideal model for evaluation of stem cell therapy for human joints.⁸⁹

Models of infectious arthritis also have been studied (see Chapter 65). For instance, studies have aimed at identifying the ability of certain medications to potentiate infection when injected along with a subinfective dose of bacteria. This work proved the clinical impression that

polysulfated glycosaminoglycans increased the chances of infectious arthritis unless given with antibiotics.^{90,91} Comparisons of various treatment methods used to treat infectious arthritis have also been performed.^{92,93}

Biomechanical Models

Computerized models currently are being developed to study joint disease not only in people, but also in horses and other animals. Specifically, these models are derived from the geometry of the joints, the forces imparted by limb loading and muscle force, and the material properties of tendons, ligaments, and articular cartilage. Consequently, joint disease can be imitated on a computer and the resulting change in joint forces determined. These

models also can be used to determine what changes in loading may be expected in horses with clinical disease. Surgical procedures can be inserted into the program, and the resulting forces evaluated.

In vivo work will not be replaced in the near future because it is the best means of evaluating tissue response to disease and treatment. However, newer in vitro systems and computer models are becoming more precise and better accepted by the research community and clinicians. In musculoskeletal modeling to characterize the forces that surround the joint⁹⁴⁻⁹⁹ the goal is to create a finite element model of the joint of interest and input various loading parameters that are seen during exercise and may lead to injury.

Chapter 65

Infectious Arthritis and Fungal Infectious Arthritis

Alicia L. Bertone and Jennifer M. Cohen

INFECTIOUS ARTHRITIS

Alicia L. Bertone

Classic clinical signs of infectious arthritis are heat and swelling and rapid development of non-weight-bearing lameness, often in less than 24 hours. The suspicion of joint infection increases if a predisposing risk factor is evident, such as prematurity, a high sepsis score, or multi-systemic disease in a foal^{1,2} or preceding joint injection in an adult horse. Fracture and nonarticular infection (cellulitis or foot abscess) need to be differentiated from infectious arthritis, because in these diseases, acute, severe lameness also develops.^{3,4}

CAUSES

Musculoskeletal infection was reported to cause death in 5.2% of 2468 foals.⁵ Yearly morbidity was 27.4% (677 foals), and morbidity attributed to musculoskeletal infection was 2.1%. Septicemia was the second most common cause of death, and hematogenous spread was the most common cause of infectious arthritis.⁶ Bacteremia with infectious arthritis in foals decreased survival.⁷ The risk of infection was highest in the first 30 days postpartum and was lowest in practices that assessed the efficacy of transfer of passive immunity. Isolation of *Salmonella* species from synovial fluid and systemic disease were associated with an unfavorable prognosis for survival.¹

In two retrospective studies of 153 mature horses^{8,9} the most common causes of synovial infection were traumatic wounds (36.5% for joints and 55% for tendon sheaths), injections (34.1% and 22%), postoperative infection (1.0% for arthroscopy,¹⁰ 19.8% overall for joints), and idiopathic

causes (9.5% and 22%).⁹ Standardbreds,⁹ draft breeds,¹⁰ and the tarsocrural joint^{9,10} were overrepresented in adult horses with joint infection, reflecting a greater number of joint injections in these breeds and this joint.

Of 424 bacterial isolates from 233 horses with joint, tendon sheath, or bone infection, 91% were aerobic or facultative anaerobes. The most common organisms were Enterobacteriaceae (28.8%), followed by streptococci (13%) and staphylococci (11.8%).¹¹ In foals, Enterobacteriaceae including *Escherichia coli* and *Staphylococcus* species^{1,12} were more likely to be isolated. Staphylococci, specifically *Staphylococcus aureus*, are the most common organisms isolated from infections occurring after surgery or injections. Foals or horses with infectious arthritis secondary to penetrating wounds are likely to have multiple bacterial infections. *Clostridium* species have been isolated from foals¹³ and were the most common anaerobes isolated, particularly from wounds near the hoof.¹¹ Fungal or mycobacterial organisms are a rare cause of infectious arthritis but can be considered pathogens if identified in pure culture more than once (see later).^{14,15} Reactive arthritis in foals with septicemia from *Rhodococcus equi* or subsequent to injection reactions can be confused with infectious arthritis, but lameness usually is not prominent, and synovial fluid nucleated cell counts are often within normal limits.^{16,17}

EXAMINATION AND INITIAL MANAGEMENT

Potential infectious arthritis must be considered an emergency and is treated most effectively with early diagnosis. A systematic approach should include hematological examination; measurement of plasma fibrinogen; synovial fluid analysis, including cytological examination, Gram stain, and synovial fluid culture (up to 5 mL of synovial fluid in a broth culture bottle); and radiography.³ In foals, particularly those with abnormal sepsis scores, blood culture should be performed simultaneously. In adult horses, systemic blood examination is less rewarding than in foals, particularly in the early phases of clinical signs. In horses with experimental infectious arthritis, elevations in leukocyte count and total protein and fibrinogen concentrations have been found to take several days to develop and were changed significantly from baseline values for individual horses, but they remained in the normal range

for all horses.¹⁸ Before arthrocentesis is performed, surgical scrub materials, sterile gloves, needles, syringes, broth culture bottles, ethylenediamine tetraacetic acid (EDTA) or heparin tubes for cytological examinations, smear slides for Gram stain, and a dose of antimicrobial agents to instill directly into the joint after sampling should be available (see the following discussion).

Adult horses should be sedated. Foals can be placed in lateral recumbency with administration of an α_2 -agonist and synthetic narcotic combination. Although data suggest that aseptic preparation of unclipped hair may be adequate and may significantly decrease bacterial counts on the skin,¹⁹ clipping the site for arthrocentesis is strongly recommended. In horses with periarticular wounds, arthrocentesis should be performed well away from the wound to avoid the risk of joint contamination, if the joint is not contaminated already from the wound. To determine if a joint and wound communicate, the clinician should infuse 50 to 200 mL of balanced electrolyte solution into the joint after a synovial fluid sample has been obtained for culture and cytological examination. The clinician should watch closely for leakage of fluid from the wound. This is easier than using blue dye injections or contrast radiography. The joint should be drained and antibiotic instilled into the joint after samples have been obtained and any lavage or injection of fluid completed. Samples should be submitted immediately for evaluation.

If the joint fluid is grossly cloudy, turbid, or flocculent, broad-spectrum antibiotics initially should be given intravenously (IV), and ingress and egress or through-and-through lavage of the joint should be performed until diagnosis of infectious arthritis can be confirmed. Antibiotic should be instilled into the joint after lavage has been completed. If a wound or puncture is the inciting cause, endoscopic evaluation of the synovial cavity is recommended. In one study of 95 contaminated or infected joints, 43% had intraarticular foreign material found at endoscopy.²⁰

DIAGNOSIS

Gross evaluation of the synovial fluid can be informative. If newspaper print cannot be read through the fluid sample, it probably has a cell count of at least 30×10^9 nucleated cells per liter. Fluid from infected joints is usually turbid, cloudy, and watery. Flocculence develops in chronically infected joints or joints that have been invaded with a needle or surgery. Blood contamination makes gross assessment of synovial fluid difficult, and determining if infection is present without clinicopathological analysis is often impossible. Serosanguineous fluid commonly is obtained from infected joints (Figure 65-1). An estimate of the amount of blood (packed cell volume [PCV]) or red blood cell count) can be made to correct for the number of nucleated cells contaminating the sample (hemorrhage from arthrocentesis or leakage of blood from the infection):

$$\frac{\text{PCV (\% of synovial fluid)}}{\text{Actual or estimated PCV (\% of blood)}} = \frac{\text{X (WBCs} \times 10^9/\text{L in synovial fluid)}}{\text{Actual or estimated WBCs} \times 10^9/\text{L blood}}$$

where WBCs are white blood cells.

Synovial fluid nucleated cell count, differential cell count, and total protein concentration are the most useful

Fig. 65-1 • At postmortem examination, hemorrhagic synovitis associated with acute joint infection is seen in this tarsocrural joint.

parameters to evaluate in diagnosing infectious arthritis. Although other biomarkers, such as lactate, metalloproteinases, and myeloperoxidase activity, have been found to be increased in synovial fluid from infected joints, most correlate with the nucleated cell count.^{18,21,22} Synovial fluid nucleated cell counts in excess of 30×10^9 cells/L, with more than 80% neutrophils, or total protein concentration in excess of 40 g/L are considered consistent with infection, particularly if these synovial fluid parameters correlate with clinical signs and predisposing circumstances.^{3,23} The likelihood of isolating the causative organism is correlated positively to the nucleated cell count—that is, higher nucleated cell counts are associated with greater isolation rates.²³ Approximately 25% of samples from horses suspected of having infectious arthritis have bacteria on Gram stain, confirming infection and offering the added benefit of assisting with identifying the organism and the initial selection of an antimicrobial agent.¹⁸

For horses that do not meet obvious criteria for infectious arthritis, assessment of all parameters is necessary to conclude that the joint is infected. It is important to note that joints can be infected with nucleated cell counts lower than $30 \times 10^9/\text{L}$. Infection should be suspected if nucleated cell counts are $10 \times 10^9/\text{L}$ to $30 \times 10^9/\text{L}$ and fluid is not serosanguineous, clinical signs of substantial lameness exist, fluid is flocculent (coagulating cells may falsely lower the measured cell count), a predisposing cause for infection is present (septicemia, surgery, or joint injection), and protein concentration exceeds 40 g/L. Previous intraarticular treatment with corticosteroids may delay onset of clinical signs and confuse interpretation of nucleated cell counts and total protein concentration in the acute phase.^{24,25}

Synovial fluid protein levels continue to increase in chronically infected joints to more than 60 g/L in some horses.¹⁸ Few other differential diagnoses, other than infection, produce significant elevations in total protein concentration (>50 g/L). Isolation of a pure culture of a single organism, particularly a known pathogen, such as a coagulase-positive *Staphylococcus* species, almost always indicates infection is present, even if the nucleated cell count is low.

In horses with chronic infectious arthritis refractory to aggressive treatment, nucleated cell counts can be low (5

to $10 \times 10^9/L$), but organisms, usually *Staphylococcus*, can still be isolated. In these horses the synovial fluid protein values are often high (>50 g/L) and other clinical signs of infectious arthritis (lameness, effusion, and heat) persist. In my experience these are horses that developed infectious arthritis after injection with a corticosteroid, were treated with systemic antibiotics and lavage but not aggressive drainage, have a nidus of infected subchondral bone that keeps seeding the joint, or have a joint with severe cartilage erosion.

The distribution of nucleated cells in synovial fluid is an important aid to diagnosis. In horses with early infectious arthritis, nucleated cells almost always consist of more than 80% neutrophils and commonly more than 90% neutrophils. The neutrophils usually appear healthy and not degenerate, although in overwhelming or aggressive infection, degeneration of neutrophils is seen. If synovial fluid has less than 75% neutrophils, infection is usually resolving.

Techniques that may be useful clinically in the future for diagnosis include polymerase chain reaction (PCR) analysis for detecting base pairs of bacterial or viral DNA in the synovial fluid^{26,27} and determining enzyme and cytokine release that may be compatible with infection.²⁸⁻³⁰ Benefits of PCR include rapid (<24 hours), sensitive testing that can detect selected species of bacteria in the presence of antimicrobial drugs. PCR diagnostic techniques are sensitive because they amplify small quantities of bacterial DNA. Inherent in high sensitivity, however, is a possible high false-positive rate, because of skin contamination or contamination with bacteria at the time of arthrocentesis. Future clinical use and evaluation of this technique are expected.

Identification of enzyme/cytokine ratios or quantity may be specific for infection, because infection is the largest joint challenge that exists. Knowledge of the presence and interaction of mediators and inhibitors in joints is growing rapidly and is an active area of research. For further information on this aspect of joint infection, the reader is referred to other publications.^{28,30}

It is important to determine whether bone or physal involvement is concomitant, particularly in foals with refractory infectious arthritis. In most foals with bone involvement, radiolucent changes occur rapidly and are often detectable within 1 week after onset of clinical signs. In most bones, radiological changes may be apparent in 7 to 10 days, but if the small cuboidal bones of the carpus or tarsus are involved, the clinician may face an even greater diagnostic challenge. Infarction associated with infection may slow bone resorption, and evidence of radiolucency may lag for several days.

Nuclear scintigraphy may be useful to locate foci of infected bone, particularly in identifying involvement of subclinical sites of infection in polyarthritic foals, but the technique has practical restrictions. Normal bone scans or radiolabeled white cell studies can be performed (see Chapter 19). The foal becomes radioactive, and handling of the foal, blood samples, and synovial fluid samples poses a small risk to attendants. In addition, if the joints surrounding the small bones are infected, the resolution of the scan may be inadequate to identify specific bone involvement. Magnetic resonance imaging offers promise of improved identification of osteomyelitis^{31,32} and has

become available at many referral hospitals. Osteomyelitis is present in up to 59% of foals with infectious arthritis, but a favorable prognosis still can be achieved with treatment,¹ although the prognosis for athletic function is reduced when adjacent bone is involved or infectious arthritis is protracted.

In adult horses with acute-onset lameness associated with a wound, radiological examination should be performed to rule out the presence of radiodense foreign material or concurrent traumatic osseous injury. In the absence of a wound, if lameness has already been present for some days, radiological examination is warranted to determine if there are any bony changes, which will prompt early arthroscopic evaluation and debridement. Radiological examination is also indicated in a horse that has failed to show progressive improvement after instigation of appropriate management. The presence of radiolucent areas is indicative of likely bone infection, which warrants a more guarded prognosis, especially if progressive.

ANTIMICROBIAL THERAPY

Systemic Therapy

Intravenous antimicrobial therapy should be initiated immediately, before bacterial culture results are available. Systemic administration of broad-spectrum antimicrobial drugs should be combined with the local administration of antimicrobial agents. Most common combinations include penicillin with an aminoglycoside or a third-generation cephalosporin such as ceftiofur sodium or cefotaxime.³³ In a retrospective study of equine musculoskeletal infections, gentamicin and amikacin were effective against 85% and 95% of equine isolates, respectively, indicating that they are good choices for initial combination therapy.¹¹ Antimicrobial drugs given orally should be reserved for infection that is resolving, because gastrointestinal absorption is erratic, and blood and tissue levels are lower. Oral enrofloxacin is used to treat chronic bone and synovial infections in mature horses without reported incident, but enrofloxacin is not currently approved for use in horses. Enrofloxacin (Baytril 100) administered IV at 5 mg/kg once daily is effective and safe in mature (3 years of age and older) horses.³⁴ Enrofloxacin may cause lameness and cartilage lesions in foals and should not be used.³⁵ Enrofloxacin should not be administered to lactating mares, because the milk may concentrate the drug and subject the foal to chondrotoxic doses. (Editor's note [MWR]: In several horses orally administered enrofloxacin has not been effective at managing infectious arthritis, even when testing has suggested that in vitro susceptibility is present.)

Antimicrobial drugs should be given IV and in general at a dosage interval that maximizes peak serum levels and sustains trough levels that are at or above the minimum inhibitory concentration (MIC) for the isolated organism. Serum antimicrobial peak and trough measurements should be periodically checked to maximize effectiveness and minimize toxicity (see the following discussion).

Aminoglycoside administered once daily may be most effective, producing a large serum aminoglycoside concentration and a greater bactericidal effect than more frequent administration.³⁶ The aminoglycoside postantibiotic effect (duration of sustained antimicrobial killing) is concentration dependent. With a single daily dose, trough levels are

lower than with repeated administration, thus lowering the risk of toxicity. Using *in vivo* models of infectious osteomyelitis, improved efficacy of gentamicin was demonstrated using once-daily administration (6.6 mg/kg body mass IV) compared with three-times-a-day administration (2.2 mg/kg body mass IV). In normal horses, gentamicin (administered at 6.6 mg/kg body mass once daily for 10 days) did not induce signs of nephrotoxicity and prolonged the postantibiotic effect.³⁷ Therefore gentamicin and other aminoglycosides should be administered once daily in horses. However, the pharmacokinetics of aminoglycosides are altered in septic and premature hypoxic foals.³⁸ Serum drug concentrations should be measured to adjust dosage intervals. Sepsis score and creatinine concentration are inversely correlated to amikacin clearance in foals and could be useful indicators of altered drug disposition and delayed clearance.³⁹ The dosage interval may need to be lengthened beyond 24 hours in these foals to avoid toxicity because of higher trough concentrations. In septic neonatal foals, administration of gentamicin at 3.3 mg/kg twice daily IV produced peak serum concentrations of more than 6 mcg/mL and trough concentration less than 2 mcg/mL in all foals without toxicity or development of new sites of infection.⁴⁰

The drug must have excellent diffusion into the joint.⁸ Most antimicrobial drugs penetrate the synovium in therapeutic concentrations when administered systemically at recommended doses.⁴ Concentrations of aminoglycosides actually may be greater in inflamed joints compared with normal joints.⁴¹ If systemic blood trough levels drop below the MIC for that antimicrobial drug, synovial fluid concentrations may also drop below the MIC. Local antimicrobial drug administration (intraarticular), used to sustain high drug concentrations at the site of infection, may be most effective in both killing bacteria and penetrating organic debris.

Most positive synovial fluid cultures will be so within 24 hours after onset of infection, and a Gram stain can be immediately helpful. An additional 24 hours is usually needed to confirm the identity and susceptibility pattern of the organism. In my opinion, a broad-spectrum antimicrobial drug should be administered initially and continued at least until clinical signs begin to resolve substantially. Some joints may contain single or several organisms that were not isolated, particularly if infection was caused by a wound or by septicemia. Joints may be open, or repeatedly invaded during treatment, or a foal may be at risk for continued showers of bacteremia, thereby increasing the risk of a shift in causative organism in the middle of treatment.

Local Therapy

For years local administration of antimicrobial agents was considered taboo, because solutions varied in pH and were believed to be injurious to tissues. The deleterious effects of local antibiotic administration were greatly overemphasized, and one of the most substantial advances in the management of horses with infectious arthritis and osteomyelitis has been the implementation of local antimicrobial therapy. High tissue concentration of antimicrobial agents causes rapid elimination of joint and bone infections.^{42,43} Many innovative methods are being explored to provide high local antimicrobial drug levels. Administration of

systemic antimicrobial agents remains an important adjunctive therapy, but it is recognized that tissue concentrations at the site of infection may be considerably lower than those achieved with local administration of drugs (at or below the MIC for the organism), and therefore systemic administration is less effective.⁴⁴

Direct Local Infusion of Antimicrobial Drugs

Intraarticular injection of antimicrobial drugs into an infected joint every 24 hours is effective for early infectious arthritis. Intracarpal administration of 150 mg gentamicin has been found to maintain synovial fluid gentamicin concentrations well above the MIC for most equine pathogens (2 mcg/mL) for 24 hours.^{42,45} Most antimicrobial drugs, including penicillin, the cephalosporins, and aminoglycosides, are minimally irritating.

Appropriate intraarticular doses of antimicrobial drugs are not scientifically identified, but anecdotally up to 500 mg gentamicin, 250 mg amikacin, 1×10^6 units of sodium penicillin, 500 mg cefazolin, and 500 mg ceftiofur sodium have been used without reported difficulties. Fluoroquinolones should not be used because at high concentrations the drugs are toxic to chondrocytes.⁴⁶

Topical lavage of an infected joint or osteomyelitic bone is beneficial for the removal of infected organic debris, destructive enzymes, and neutrophils, but the inclusion of antimicrobial or antiseptic compounds in the lavage solution is still of questionable benefit. An increase in the local antimicrobial drug concentration is expected after lavage with antimicrobial drugs, but most of the drug leaves the joint with the lavage solution. Injection of antimicrobial drugs at the termination of lavage is probably more efficient. Use of antiseptics and potentiated antiseptics (EDTA and Tris buffer) in lavage may kill surface bacteria, but sustained killing is expected to be limited.⁴⁷ Even dilute antiseptic compounds such as 0.05% chlorhexidine can be irritating to equine joints.⁴⁸

Antimicrobial-Impregnated Biomaterials

One of the most practical methods for maintaining slow but effective release of antimicrobial agents in bone and joint infections is the intraarticular insertion of impregnated polymethylmethacrylate (PMMA) beads.⁴⁹ In a study of 1085 open limb fractures in people, the postoperative infection rate was significantly reduced, from 12% to 3.7%, when aminoglycoside PMMA beads were inserted at surgery.⁵⁰ PMMA impregnated with aminoglycoside and cefazolin was used in horses with open fractures and with bone, implant, and joint infections, and survival rate was about 60%.^{51,52} In 12 horses with infectious arthritis treated with gentamicin-impregnated PMMA beads and lavage, including six with osteomyelitis, 92% survived.⁵³ Several antimicrobial drugs were shown to elute from PMMA in active concentrations, including aminoglycosides such as amikacin and gentamicin, and fluoroquinolones such as ciprofloxacin.^{43,53-55} Use of fluoroquinolones in PMMA is not currently recommended in joints, because the concentrations expected to be released with local therapy may be toxic to equine chondrocytes.⁴⁶

Implants (beads) can be prepared in the operating room, or beads can be gas sterilized and stored for future use. The antimicrobial compound (1 or 2 g of powder or liquid) is mixed thoroughly with 20 to 40 g of PMMA

(medical grade) and shaped as desired. Beads can be placed on suture material to assist with retrieval from the joint. The beads can be placed into the joint through an arthrotomy, which is usually left open to drain. If infection recrudesces, existing beads can be exchanged with fresh ones or with those impregnated with different antimicrobial agents. Small beads (4×6 mm) can be placed through arthroscopic portals or cannulas, thus avoiding arthrotomy. Arthrotomy, however, can also assist with joint drainage if left open to heal by contraction and epithelialization. In my experience, if infection is rapidly eliminated, the beads can be difficult if not impossible to retrieve. Beads frequently migrate to a joint pouch and become enveloped by synovium. If the arthrotomy heals quickly, the beads may need to be removed surgically. Occasionally beads well removed from articular surfaces can be left in place permanently. Long-term sequelae appear minimal, but studies to date have not been performed. Complications with PMMA implants include the use of too many or too large beads, causing soft tissue trauma and pain, failure to exchange beads in unresolving infection, and placement of beads under tendons and on articular cartilage. If osteomyelitis exists, lesions can be debrided and lavaged, and beads can be implanted directly into the bone bed. Beads placed directly into bone lesions are usually removed without difficulty.

Addition of antimicrobial compounds to PMMA alters the biomechanics of PMMA, particularly when liquid forms are used. For purposes of treating joint infection, accuracy in drug elution and biomechanical properties of the PMMA are not critical. Use of the PMMA in orthopedic implants may require more precise preparation of implant material. The elution rate of antimicrobial drugs varies with size and shape of the implant, the amount of antimicrobial agent impregnated, and the type and form of antimicrobial drug selected and depends on thorough and even mixing of the formulation.

Antimicrobial-Impregnated Biodegradable Drug Delivery Systems

Although PMMA offers advantages for local antibiotic delivery, its permanency is not ideal, particularly for certain tissue types. Many biodegradable compounds have been investigated as possible implants for antimicrobial drug delivery, most notably collagen,^{56,57} DL-lactide-glycolide copolymers, polyanhydrides, polylactide, sebacic acid, tricalcium phosphate and calcium carbonate bone cement, and plaster of Paris.⁵⁸⁻⁶³ Because of the ongoing degradation a greater amount and duration of antimicrobial drug release can be achieved. In a study using rabbits with infectious osteomyelitis, bacterial counts were significantly lower in those treated with gentamicin-polyanhydride implants than in those treated with gentamicin-PMMA implants.⁶⁰

In horses, 50:50 DL-lactide-glycolide copolymers and poly(DL)lactide impregnated with gentamicin that eluted for 10 days eliminated infection of synovial explants in vitro without significant detrimental effects on synovial cell function (hyaluronan production), morphology, or viability.⁵⁸ In horses with experimentally induced *Staphylococcus* joint infection, intraarticular treatment with C44 fatty acid-sebacic acid (1:1) beads impregnated 20% with gentamicin as the sole treatment effectively eliminated joint infection in 33% of joints by day 3 and 66% of joints

by day 13.⁶² Lameness significantly improved. Gentamicin concentration peaked at 82 mcg/mL at 24 hours after insertion of beads and remained higher than 10 mcg/mL for 12 days (range of 5 to 41 times the MIC for the organism).⁶² Currently these implants are being investigated for clinical use, but they are not yet commercially available. Plaster of Paris beads may offer a practical option for degradable implants, but biocompatibility studies should be performed.⁶³

Regional Perfusion

Regional perfusion can be used to deliver therapeutic concentrations of antimicrobial agents to a selected region of the limb, usually using the venous system for drug administration with horses under anesthesia or sedated. Drugs also can be administered using an intraosseous route.⁶⁴ In either case a tourniquet is applied proximal to the infected bone or joint for approximately 30 minutes (Figure 65-2). Concentrations of gentamicin obtained in synovial fluid rose to a peak of 589 mcg/mL immediately after regional perfusion and declined to 4.8 mcg/mL at 24 hours.⁶⁵ This technique was used to decrease WBC numbers in infected synovial fluid in experimentally induced equine arthritis and is most practical if applied when the horse is anesthetized for other treatment of infection, such as debridement and lavage, when intraosseous infusion can be performed simultaneously.⁶⁶ Advantages of this technique include the use of antimicrobial drugs that may be toxic if administered systemically (vancomycin)⁶⁷ or directly into the joint (enrofloxacin),⁶⁸ the ability to repeat daily injections, and distribution to the entire limb including bone. Limitations include the development of vasculitis, difficult identification of the vein, and the discomfort of a tourniquet and infusion of antimicrobial drugs. Perineural analgesia can be performed. Intraarticular antimicrobial drug concentrations using intravenous regional infusion are

Fig. 65-2 • Use of regional limb perfusion to deliver an antimicrobial drug into an infected tarsocrural joint. The tourniquet above the joint permits retrograde infusion of the saphenous vein. Concentrations of antimicrobial drugs above the minimum inhibitory concentration for most organisms that cause musculoskeletal infection can be maintained for 24 hours. The tourniquet is maintained for 30 minutes and then removed.

not as high as those obtained with direct intraarticular injection.^{45,69}

Bone concentration of antimicrobial agents is similar after intraarticular injection or regional perfusion.⁶⁹ In foals with infectious arthritis and adjacent osteomyelitis, either delivery method should effectively provide bone antimicrobial concentrations, but for foals with numerous joint or bone sites affected, regional perfusion offers an advantage. Intraarticular administration relies on drug diffusion through cartilage or local blood supply to reach bone. Caution should be used when applying tourniquets in foals, because even short durations of application can induce clinical signs of distal limb ischemia. In foals with compromised bone blood flow from swelling and toxic effects of infection, this may be detrimental. I have seen two foals develop severe osteonecrosis after repeated regional perfusion procedures, a complication attributed to tourniquet application.

Balloon Constant Rate Infusion Systems

Constant rate infusion (CRI) of antimicrobial drugs, with or without local anesthetic solution, can be administered by commercial systems designed to deliver a constant rate of a therapeutic agent. These systems typically come as kits, and tubing is placed intraarticularly, usually at the initial arthroscopic evaluation and debridement of the infected joint. The reservoir (balloon) for the therapeutic agent(s) can be secured to the limb and aseptically refilled as needed (Figure 65-3). These systems have been reported to provide a clinical response and long-term outcome similar to other techniques for treatment of equine infectious synovitis.⁷⁰ Use of local anesthetic solution in CRI systems is controversial for joints because both lidocaine hydrochloride and mepivacaine hydrochloride have demonstrated chondrocyte toxicity when in direct contact in culture.^{71,72}

Fig. 65-3 • A horse with an infected tarsocrural joint with a constant rate infusion balloon system installed to deliver an antimicrobial drug directly into the joint. The reservoir balloon is refilled daily.

JOINT DRAINAGE AND DEBRIDEMENT

Joint lavage and drainage are vital for the effective management of infectious arthritis.^{1,4,6,8,20} Ideally, arthroscopic evaluation should be performed to remove foreign material and fibrin and to assess cartilage health. Removal of angry, infected synovium may reduce bacterial count and a source of infection. Healthy synovium should not be removed, because it may help combat the infection and may normalize joint health. In horses, maximal synovectomy has been found to be no better than open arthrotomy for management of infectious arthritis.⁷³ After synovectomy villous structures may not be regained for many months.⁷³⁻⁷⁶ Repeated through-and-through lavage using needles placed on opposite sides of a joint can be effective in eliminating infection in some horses, but the lavage fluid may completely bypass some areas of a joint, allowing the infection to persist. Arthroscopy permits more thorough lavage of the entire joint, and together with a form of continued joint drainage, provides the most complete and rapid method to remove infective material and to estimate the extent of damage.^{4,8,20}

Arthroscopic portals can be enlarged to function effectively as open arthrotomy incisions for continued drainage, or closed suction drainage can be initiated. The goal of either technique is continued joint decompression and drainage. Arthrotomies usually heal without complication and with minimal scarring. With continued infection, arthrotomies stay open and may develop excessive granulation or fibrous tissue, but this complication may occur with other methods of chronic drainage as well. Open drainage in joints that cannot be bandaged, such as the stifle, can be performed by tying up the horses using cross-ties or an overhead wire. Adhesive bandages applied using ether can be used to cover open drainage sites. I have not seen substantial permanent complications associated with arthrotomy and open drainage. Open arthrotomy can be used to insert PMMA beads for treatment of osteomyelitis or in horses with refractory infection.

Properly managed closed suction drainage is useful for large joints such as the tarsocrural and scapulohumeral joints, using a flat, fenestrated, latex drain. The drain should be tunneled under the skin to exit at a site removed from the joint. Negative pressure is applied using a large syringe, with a large guarded needle passed through the syringe to keep the plunger retracted.⁷⁷ The syringe is evacuated several times a day, and the drain is left in place until only small volumes of fluid are collected or the fluid appears relatively normal grossly and cytologically, and lameness improves. If the suction system fails, the drain is removed.

After initial debridement, lavage, and establishment of drainage, the joint can be flushed and local antimicrobial drug therapy applied daily, usually for 3 days. If clinical improvement is dramatic, further lavage is optional, but local antimicrobial injection should continue for 3 days. If clinical improvement continues, local antimicrobial therapy is discontinued. The joint is then rested for 24 hours and the synovial fluid is reassessed. Ideally, follow-up synovial fluid contains fewer than 15×10^9 nucleated cells/L, but irritation from aggressive lavage and intraarticular antimicrobial compounds can result in higher cell counts.

Fig. 65-4 • Craniocaudal radiographic image of a foal's stifle joint demonstrating radiolucency of the medial tibial plateau (solid black arrows) that was debrided arthroscopically and a singular polymethylmethacrylate bead (open arrows) was placed intraarticularly.

Clinical improvement is assessed by evaluating rectal temperature, lameness, and heat over the joint surface. The synovial fluid nucleated cell counts should decline slowly over the next 7 days if infection remains under control. If nucleated cell counts rise again or if lameness recurs, lavage and local antimicrobial therapy can be reinstituted. Having to perform two series of lavage procedures (3 days each time) in foals is typical.

Articular Osteomyelitis

Fifty percent of foals with infectious arthritis also have osteomyelitis or bone necrosis.^{1,8,9,13} Usually bone is infected, but bone infarction can also occur. These foals are best treated using arthroscopic debridement, and joint infection usually clears within days of removal of infected bone. The importance of arthroscopic debridement cannot be overemphasized. In young foals with severe joint distention, lesions that would not normally be amenable to arthroscopic evaluation and debridement become accessible, such as those involving the tibial plateau (Figure 65-4), caudal aspect of the humeral head, or coxofemoral joint. In my experience infection or necrosis of the tarsal bones and some aspects of the carpal bones is the most difficult to treat, because they are not directly accessible using arthroscopy. Insertion of PMMA beads close to the distal tarsal joints and prolonged systemic antimicrobial administration may be successful.

In adult horses with articular osteomyelitis it is critical to debride the infected bone as soon as the condition is recognized radiologically (Figure 65-5). In chronic, progressive, infectious osteomyelitis in adult horses, arthrodesis,

Fig. 65-5 • Dorsolateral-palmaromedial radiographic image of a carpus of a Standardbred racehorse with infectious osteomyelitis and necrosis of the dorsomedial aspect of the third carpal bone. The infection occurred subsequent to an intraarticular injection.

joint resection, or stimulated ankylosis with a bone graft may be the only way to eliminate joint pain.⁷⁸⁻⁸¹ Infection of implants does not always occur. Bone infection can resolve with prolonged antimicrobial drug therapy, but joint immobilization is important to assist with elimination of infective organisms.

PAIN MANAGEMENT

Nonsteroidal Antiinflammatory Drugs

In a rabbit model of infectious arthritis caused by *Staphylococcus*, use of nonsteroidal antiinflammatory drugs (NSAIDs) with antimicrobial drugs significantly reduced joint swelling, prostaglandin E₂ release, and collagen joint destruction compared with the administration of antimicrobial drugs alone.⁸² In mature horses phenylbutazone administration (4.4 to 8.8 mg/kg body mass daily) is commonly used to reduce pain and joint inflammation. Risk of laminitis in the supporting limbs of lame horses is an important consideration in treatment of infectious arthritis. Cyclooxygenase-2 (COX-2) inhibitors are approved for use in horses and seem promising at reducing the risk of toxic side effects, such as gastrointestinal ulcers and nephrotoxicity, seen with currently marketed NSAIDs.⁸³ COX-2 inhibitors reduce the production of inducible prostaglandin E₂ without suppressing the constitutive form of prostaglandin E₂ that protects epithelial mucosa homeostasis. Administration of NSAIDs in horses with infectious arthritis must be titrated to allow for the accurate assessment of joint pain as an indicator of clinical response to treatment. Most currently available NSAIDs marketed for use in horses, or used off label in horses, have been demonstrated to suppress equine synovial membrane inflammation and prostaglandin E₂ release in culture experiments.^{84,85}

Dimethyl sulfoxide (DMSO) solution (10% to 40%) has been used experimentally to treat synovitis and clinically to treat infectious arthritis in horses.⁴ Lavage or

intraarticular injection of up to 40% DMSO does not appear to have clinically significant negative effects on articular cartilage. DMSO is a free radical scavenger, antiseptic, and analgesic and may inhibit chemotaxis of inflammatory cells. Practically, DMSO can be used in lavage fluid, particularly in the last liter of lavage. Because of the high solubility of DMSO, some residual drug probably is absorbed into the synovium during lavage.

Epidural Narcotics

Placement of indwelling epidural catheters and chronic infusion of α_2 -agonists and narcotics such as morphine have been useful in alleviating hindlimb lameness and in horses with severe pain secondary to infectious arthritis (see Chapter 85).^{86,87} In horses with chronic osteomyelitis or refractory infectious arthritis, this technique may be useful in preventing recumbency or supporting limb laminitis.

TOPICAL TREATMENT, BANDAGING, AND ALTERNATIVE THERAPY

Diclofenac topical medications can be directly applied to swollen and painful joints as antiinflammatory agents. DMSO applied topically to horses with experimentally induced carpal synovitis has significantly reduced synovial fluid nucleated cell counts.⁸⁸ DMSO was detectable in the synovial fluid of five of six horses and in the plasma of one of six horses, indicating its penetration of the tissues from topical application.⁸⁸ Topical application over infected joints may reduce synovitis.

Pressure bandages applied to reduce swelling also can reduce joint pain. Edema formation can be overwhelming in horses with infected joints and produce stiffness, discomfort, elevated synovial fluid production (joint pressure), and poor joint clearance of infected material through the lymphatic system. Pressure bandages should be sterile, particularly when covering open arthrotomy incisions.

Once acute inflammation has resolved, passive flexion is indicated to enhance lymph flow, improve drainage, reduce edema, and enhance joint range of motion. Capsulitis associated with infection can be a substantial complication, and physiotherapy to restore joint function can be critical to improving long-term outcome and joint motion.

PROGNOSIS

Adult horses with infectious arthritis have a good prognosis for survival and for return to athletic function, provided that infection is recognized early. In most horses infection is eliminated.^{4,8,9,53} Preexisting osteoarthritis and articular cartilage damage are the most common reasons for failure to return to performance. Prompt recognition, aggressive drainage and lavage, and early treatment with local antimicrobial drugs have steadily improved prognosis to more than 80%⁸ and hopefully success rates close to 100% will be possible. Aggressive surgical debridement and use of implantable elution materials for chronic administration and multiple site delivery of antimicrobial agents have improved prognoses. The prognosis in foals is more guarded. In one study septicemia, osteomyelitis, and hypogammaglobulinemia resulted in a lower prognosis for life in foals compared with adults, and infection was eliminated

in only 50%.⁹ In other studies of neonates^{1,13} and adult horses,⁸ elimination of infection was achieved in 70%,^{1,8} 50% survived,^{8,13} and 30% reached racing performance.¹

FUTURE TREATMENTS

Newer biodegradable polymers impregnated with antimicrobial drugs for direct joint insertion through an arthroscopic portal could greatly enhance the process of sustained drug delivery. Arthroscopic instrumentation can be used to insert the beads into the joints of standing horses.

Medical therapies for intraarticular drug therapy in the future may focus on prevention of *S. aureus* adhesion. A prominent feature of *S. aureus* virulence is the production of a bacterial surface marker that recognizes adhesive matrix molecules in collagen, precipitating bacterial adherence.^{89,90} Monoclonal antibody, receptor antagonists, and vaccination challenges reduce the risk of acquiring infection with *S. aureus* in experimental animals.^{89,91} These therapies may also be useful in the horse, because *S. aureus* is the most common cause of joint infection in adult horses.

FUNGAL INFECTIOUS ARTHRITIS

Jennifer M. Cohen

LITERATURE REVIEW

Unlike bacterial infectious arthritis, which occurs commonly in horses,¹⁻⁴ there are few reports in the equine literature describing infectious arthritis caused by fungi. As with bacteria, fungi can invade a synovial structure by direct inoculation from an exogenous source (secondary to trauma, surgery, or joint injection), by hematogenous spread, or by direct extension from an adjacent focus.⁵ Predisposing factors to fungal infectious arthritis in people include previous (often repeated) intraarticular injection of glucocorticoids, severe systemic illness, long-term administration of systemic antibiotics, treatment with immunosuppressive agents, joint prostheses, and intravenous drug abuse.⁵⁻⁷ In the equine literature there is reference to fungal infectious arthritis in only six adult horses and two foals.⁸⁻¹³ Of these, four had a history of previous joint injection with corticosteroids, three were systemically ill (neonatal septicemia [both foals] and gastrointestinal disease [one]), and one horse had a history of trauma.⁸⁻¹³ All horses had had previous therapy with an antimicrobial agent, and six horses had received numerous antimicrobial drugs, including systemic administration of penicillin (five), trimethoprim-sulfamethoxazole (four), amikacin sulfate (three), ceftiofur sodium (three), ticarcillin clavulanate (two), rifampin (two), gentamicin sulfate (one), chloramphenicol (one), streptomycin (one) and metronidazole (one).⁹⁻¹² Amikacin sulfate was administered intraarticularly before diagnosis of fungal infectious arthritis in two horses.^{8,12} Although certain fungal diseases have a regional (geographic) distribution, including coccidioidomycosis, histoplasmosis, and blastomycosis, no geographic predilection was suspected in the horses with intraarticular fungal infection.⁸⁻¹³ Rather, the development of fungal infectious arthritis appears to be the result of a combination of factors, including systemic or local immunosuppression (either

secondary to systemic disease or the result of corticosteroid administration) and the use of systemic or intraarticular antimicrobial therapy. These likely create an ideal environment for fungi to thrive. Weakened local immune response and lack of competition from bacterial pathogens allow opportunistic organisms such as *Candida* to colonize a joint that would normally be inhospitable.

CLINICAL SIGNS AND DIAGNOSIS

The clinical manifestation of fungal infectious arthritis closely resembles that of bacterial infectious arthritis, including severe lameness, joint effusion, and variable degrees of periarticular edema. As is true for horses with bacterial infectious arthritis,⁴ the metacarpophalangeal and the tarsocrural joints are overrepresented in horses with fungal infectious arthritis.⁸⁻¹³ Although fever (body temperature $>38^{\circ}\text{C}$) is detected in more than 50% of horses with bacterial infectious arthritis,⁴ only one of eight horses (12.5%) reported to have fungal infectious arthritis was pyrexia at the time of diagnosis.⁸⁻¹³ Radiological findings in seven horses with fungal infectious arthritis included the presence of focal subchondral radiolucency (six), periarticular bone proliferation (four), osteopenia (two), and joint space narrowing (two).⁸⁻¹³ Nuclear scintigraphy revealed diffuse increased radiopharmaceutical uptake (IRU) of all bones of the metacarpophalangeal joint, with focal intense IRU in the distal, palmar aspect of the third metacarpal bone and the proximal aspect of the proximal phalanx in one horse with *Candida utilis* infection.⁸ The reported synovial fluid nucleated cell count ranged from 15,000 to 82,000 cells/mcL (median 45,000 cells/mcL).⁸⁻¹² Synovial fluid total protein concentrations ranged from 1.8 to 5.4 g/dL (median 4.3 g/dL).^{8-10,12}

Fungal organisms were observed cytologically in synovial fluid of only one of the eight horses (12.5%) in the previous reports.⁸⁻¹³ Similarly, fungal organisms were identified using Gram stain in only 20% of people with fungal infectious arthritis.⁵ Definitive diagnosis of fungal infectious arthritis is most frequently by fungal culture from synovial fluid.⁸⁻¹³ Unfortunately, although fungi can be isolated from reduced solidified holding media and blood culture media,⁸ they are generally slow growing and it frequently takes 7 to 10 days for a positive result. During this time initiation of antifungal therapy is delayed, often resulting in exacerbation of clinical signs and hospital costs. Speciation and susceptibility testing are also slow for fungal organisms, frequently taking an additional 10 to 15 days before results are obtained. Of eight horses reported to have fungal infectious arthritis, six had infections caused by *Candida* species. There were two horses with *Candida albicans* and one each with *Candida famata*, *Candida parapsilosis*, *Candida tropicalis*, and *C. utilis*. The remaining two horses had monoarticular infection with *Aspergillus fumigatus* or *Scedosporium prolificans*. A summary of the results of in vitro susceptibility testing of horses reported to have fungal infectious arthritis is provided in Table 65-1.

MANAGEMENT

Successful management of horses with fungal infectious arthritis is dependent on the attending veterinarian's ability to make a timely diagnosis and respond with

aggressive medical and surgical therapy. Most horses with fungal infectious arthritis have chronic synovitis, fibrin accumulation within affected joints, and thickened periarticular tissues, making lavage in standing horses or using needles difficult. Arthroscopic debridement and lavage are mandatory in most horses; additional information about the integrity of articular cartilage and samples of synovial membrane and fibrin can also be obtained at the time of surgery. Although antiseptics such as povidone-iodine⁹ or antifungal agents such as miconazole⁹ are occasionally added to lavage fluids, there is no evidence that these improve outcome.

Whenever possible, medical therapy should include prolonged administration (6 to 8 weeks) of appropriate systemic antifungal agents. Antifungal drugs reported to be administered systemically in horses include amphotericin B,⁹⁻¹¹ fluconazole,⁸⁻¹⁰ ketoconazole,^{9,12} and itraconazole.¹² Systemic administration regimens previously used for amphotericin B, fluconazole, ketoconazole, and itraconazole and a suggested regimen for voriconazole are provided in Table 65-2. Although there is no published information regarding clinical use of voriconazole, pharmacokinetics after intravenous and oral administration have been established in the horse.¹⁴

Because in vitro susceptibility results may not be available for some time, initiation of empiric antifungal chemotherapy while awaiting final culture results is highly recommended. Although more fungal organisms isolated from equine joints are sensitive to amphotericin B than any other antifungal chemotherapeutic agent, use of this drug (both systemic and local) has been associated with severe undesirable side effects, making it a poor choice for initial empiric antifungal therapy. Rather, I recommend systemic administration of fluconazole or itraconazole combined with local administration of additional drugs (see later). In my experience, lameness will usually dramatically improve within 24 hours of administration of appropriate antifungal chemotherapeutic drugs even in horses with well-established infection.

Local administration of antifungal agents by intraarticular injection and regional limb perfusion are important adjuncts to parenteral therapy.^{8,10} Intraarticular administration of fluconazole (20 mg)⁸ and voriconazole (100 mg)¹⁵ has been used in the successful management of fungal infectious arthritis without known complications. Although intraarticular administration of amphotericin B has been reported in at least one horse¹⁰ and is regularly performed in people with fungal infectious arthritis,¹⁶ the drug is a well-established model for inducing chemical arthritis in the horse and its use is questionable. In horses in which amphotericin B is deemed necessary, based on the results of in vitro culture and susceptibility testing, local administration by regional limb perfusion may be preferred to parenteral or intraarticular administration. I gave amphotericin B at a dose of 5 mg, diluted in 50 mL of 5% dextrose, by regional limb perfusion on several occasions with minimal untoward side effects. Clinical improvement in conjunction with systemic and intraarticular administration of fluconazole was achieved in a horse with *C. utilis* infectious arthritis.⁸ Severe phlebitis and cellulitis were observed after regional limb perfusion with higher doses (100 mg) of amphotericin B.¹⁷ Pharmacokinetic studies examining the synovial fluid, tissue, and plasma concentrations of

IV, Intravenously; D5W, 5% dextrose solution.

*This dose of amphotericin B was associated with discomfort during administration, and thrombophlebitis, hyperthermia, and azotemia developed.

[†]Unwanted side effects observed after administration of higher doses of amphotericin B were not observed at this dose. Trough plasma concentrations of amphotericin B remained greater than minimum inhibitory concentration (MIC).

amphotericin B after regional limb perfusion have not been performed.

PROGNOSIS

Even with an aggressive multipronged approach to therapy, the prognosis for horses with fungal infectious arthritis must be considered guarded at best. Of the eight reported horses with fungal infectious arthritis, only five survived to discharge. Of these five horses, one returned to athletic

function, three were retired and used for breeding, and one was retired to pasture. However, most surviving horses had no radiological changes in the affected joints at the time of initiation of antifungal treatment, and earlier detection and treatment may have improved prognosis for athletic function. Careful cytologic examination for fungi in synovial fluid and submission of fluid specifically for isolation of fungi early in the management of horses with refractory infectious arthritis may help to diagnose fungal infectious arthritis.

Chapter 66

Noninfectious Arthritis

Alicia L. Bertone

Noninfectious arthritis is characterized by pain, heat, swelling (effusion), erythema, and lameness. Joint structure and function, aspects of diagnosis and management of joint disease, and osteoarthritis (OA) are discussed in Chapters 61 and 84. This chapter focuses on normal and abnormal joint physiology and other specific noninfectious joint diseases.

JOINT PHYSIOLOGY

Fluid flow from the vascular space into the interstitium and joint space (third compartment space) and out into venules and lymphatics is tightly governed by Starling forces, which are a balance of arterial and venous pressures and colloid osmotic forces across the joint. The resultant fluid flow through the joint is modified by permeability of the synovium (osmotic reflection coefficient) and the vessel surface area available for fluid transport (filtration coefficient). Even in normal joints these forces are influenced by gravity (joint dependency), motion (exercise), and structure (joint compliance).¹⁻⁷

Horses are unique in needing joint motion to maintain isogravitric states of the joints (no fluid gain or loss), especially in peripheral joints.¹ In normal stationary equine limbs, lymphatic drainage from joints approximates zero until joint pressure exceeds 11 mm Hg for the fetlock joint (transitional microvascular pressure). In standing animals without counter forces, such as motion or external bandages to increase lymph flow forces, gravitational pressures increase arterial pressure to the joint and venous and lymphatic pressure from the joint. The result is tissue edema and joint effusion.

JOINT PATHOPHYSIOLOGY (SYNOVITIS)

The balance of these forces is altered in horses with synovitis because of the increased blood flow, altered synovial permeability, structural joint capsular changes, and loss of joint motion because of pain.^{1,3,5,8,9} These factors profoundly affect joint physiology, contribute to clinical signs, and result in damage to the synovium and articular cartilage. Early signs of effusion that precede clinical detection of inflammation are related to changes in the hemodynamics of the joint, including increased blood flow and reduced joint motion.^{8,9}

In chronic arthritis, capsular thickening, fibrosis, and altered synovial function likely influence fluid dynamics. Capsular fibrosis and joint enlargement produce decreased tissue compliance, and an increase in intraarticular pressure occurs, even with slight increases in joint effusion.

Articular cartilage is avascular and depends on synovial fluid for nutrition, so alteration in fluid flux affects nutritional exchange between the articular cartilage and synovium. Reduced nutrition exchange to articular cartilage exacerbates articular surface fibrillation and degenerative changes.^{10,11}

PATHOLOGICAL JOINT CONDITIONS ASSOCIATED WITH ARTHRITIS

Effusion

Increased blood flow and capillary leakage occur early and contribute to increased fluid volume in the joint interstitium and synovial fluid, recognized as effusion. The condition is stimulated by vascular changes and neurotransmitter release, particularly α_2 -adrenergic stimulation.^{2,8,9} Because of low intraarticular pressures in normal equine joints (-5 mm Hg⁶; -1.25 mm Hg¹²), effusion precedes interstitial edema, until intraarticular pressure is greater than 11 mm Hg.¹ These physiological circumstances make detection of effusion one of the most sensitive indicators of early joint stress. Effusion, although common, is not normal and alters joint function. Congruent motion of joint surfaces depends on normal negative pressure and is important in decreasing shear force (side-to-side, sloppy movement).⁷ Effusion is not painful as long as capsular tension is normal. Through the phenomenon of creep-relaxation, capsular tension is reduced in distended joints. Normal joints are relatively compliant and can accommodate fairly large changes in fluid volume with minimal increase in pressure, but elastance profiles of these joints may be permanently altered.¹³ Joints with high structural congruence, such as the tarsocrural joint, are less affected biomechanically by joint effusion than are less congruent joints.⁷

High synovial fluid volume becomes more important during joint motion. Joint pressure profiles are profoundly altered by joint angle.^{6,7,13} With effusion, as initial intraarticular pressure is increased, the capacity to accommodate rapid changes in pressure goes down, causing a rapid rise in intraarticular pressure and capsular wall tension at extreme joint angles, resulting in sharp pain during maximal joint excursion and simultaneous reduction in synovial perfusion.¹⁴ These effects could be present even if synovitis is not recognized clinically. The influence of intermittent synovial ischemia is not elucidated fully, but it may be important in diseases of synovial proliferation.

Inflammation

Inflammation causes a humoral (vascular) and a cellular response. In early arthritis, cells are up-regulated to produce inflammatory mediators. Gene transcriptional profiles may be unique to certain forms of arthritis and potentially could be used in the future to recognize and prevent arthritis. Up-regulation of genes causes protein production, initiation of the inflammatory cascade, and further release of inflammatory mediators. Important mediators include cytokines interleukin-1, interleukin-6, and tumor necrosis factor.^{2,4,15,16} Secondary mediators such as the eicosanoids (prostaglandin E_2 and leukotrienes),^{2,4,15} free oxygen radicals,¹⁷ substance P_3 and nitric oxide^{3,4} are also proarthritic and amplify pain.

Cellular influx causes effusion and subsequent clinical recognition of synovitis. The degree of synovitis and articular cartilage damage are directly proportional to synovial fluid nucleated cell count in infectious and noninfectious arthritis. Neutrophils are highly migratory and can move into joint fluid within 3 hours after a chemotactic stimulus, such as with the introduction of interleukin-1, paclitaxel, or endotoxin.^{2,8,9,15,18} These cells are damaging to surrounding tissue because they have destructive enzymes and alter the synovial fluid environment. In noninfectious arthritis, nucleated cell count is usually less than 30,000 nucleated cells/mcL,¹⁵ but values greater than 100,000 nucleated cells/mcL occur in autoimmune arthritis,¹⁹ in endotoxin-induced arthritis,^{16,20} and early in reactive arthritis.

Ischemia

Intraarticular pressures greater than 30 mm Hg cause significant reduction in the perfusion of the synovium and fibrous layer of the joint capsule.¹⁴ Pressures of this magnitude occur in horses with palpable effusion of the fetlock joint and are present when synovitis is prominent.¹² Pressures greater than 60 mm Hg can reduce blood flow profoundly, and pressures approximating 100 mm Hg can cause capsule joint rupture (carpus and fetlock²¹). Clinically, joint rupture is uncommon but was hypothesized to contribute to dorsal fetlock capsular thickening.¹² I have seen this as a rare occurrence in the plantar pouch of the tarsocrural joint and the palmar pouch of the antebrachio-carpal joint. Intraarticular pressure can reach high levels during maximal flexion and extension, particularly in horses with resting pressures greater than 30 mm Hg.⁶ Ischemia has been hypothesized to be a component of synovitis, particularly in the proliferative form.²² Low oxygen tension stimulates angiogenesis and granulation tissue formation, resulting in fibrosis. In chronically inflamed joints, clubbed and thickened synovial membrane often is seen during arthroscopic surgery, supporting the concept of synovial ischemia.

Synovial Fluid Lubrication: Hyaluronan

Synovial cells produce hyaluronan. A protective layer of high-concentration hyaluronan remains close to the surface of the synovium, and the remainder diffuses into the joint space, creating the unique viscosity of synovial fluid.^{3,7} Adequate hyaluronan concentration is critical to provide lubrication of synovial soft tissues, particularly synovial villi. During inflammatory synovitis, lubrication of the soft tissues is reduced because of dilution of hyaluronan and a reduction in hyaluronan production. Swollen, edematous villi cause an elevated coefficient of friction. In horses with mild effusion, hyaluronan concentration can be normal because increased production by synovial cells matches elevation in synovial fluid volume.²³ When inflammation increases, synovial cell production decreases and degradation of hyaluronan increases. In horses with severe joint inflammation or hemarthrosis, hyaluronan concentration may be negligible.

Pain in Arthritis

Sensory and motor innervation help maintain joint stability, and in the absence of these protective reflexes, severe arthropathy may develop.²⁴ When activated, the peripheral nervous system can initiate the major features of acute

inflammation, such as vasodilation and effusion, and lower the threshold for pain.²⁵ The C and A nerve fibers responsible for pain sensation in arthritis are activated by amines (such as serotonin) and neuropeptides (calcitonin gene-related peptide and substance P) that also act locally to exert proinflammatory effects on synovium. A role of substance P in joint pain is supported by the clinical effectiveness of the substance P-depleting substance, capsaicin. Capsaicin initially activates C fibers, resulting in substance P release and pain, but subsequently desensitizes or causes degeneration of C fibers.²⁶

The contribution of neuropeptides may be different in acute and chronic inflammatory arthritis. Edema formation in denervated limbs may indicate that loss of sensory innervation could play a role in acute arthritis.²⁷ Increased edema formation and decreased permeability to macromolecules have been observed in denervated limbs subjected to interleukin-1 induction of synovitis.² The role of innervation in chronic arthritis is complex, because the neuropeptide substance P and calcitonin gene-related peptide were increased in sciatic nerve, dorsal root ganglia, and periarticular tissues but were decreased in synovium.

The therapeutic implications are intriguing. Intramuscular gold or topically applied capsaicin could selectively destroy C fibers, thus lowering substance P levels, and these have been found to be clinically useful. Nonsteroidal antiinflammatory drugs (NSAIDs) decrease prostanoid production, and intraarticular corticosteroids inhibit the arachidonic acid cascade, thus having direct and indirect effects.²⁸ In addition, stimulation of primary afferent nociceptive fibers causes release of glutamate and substance P from central spinal pathways. This nociceptive input can be inhibited by stimulation of proprioceptive and tactile type I and II fibers. Stimulation of these fibers can be accomplished by high-frequency, low-intensity transcutaneous neural stimulation, frequently used in physiotherapy.

AUTOIMMUNE-MEDIATED ARTHRITIS

Rheumatoid arthritis is a steroid-responsive arthritis, associated with high synovial nucleated cell counts, progressing to bone erosion and pannus formation. For establishment of a diagnosis of rheumatoid arthritis, an autoimmune component and production of rheumatoid factor must be documented. According to these criteria rheumatoid arthritis has not been reported in horses. In human systemic lupus erythematosus (SLE), systemic disease is also present, and autoantibodies are directed toward nuclear cellular material. An SLE-like disease has been described in a young horse.²⁹ In horses, anti-collagen type II antibodies and immune complexes have been identified in synovial fluid of horses with OA and joint trauma. However, these immune complexes are much less common in horses with mild synovitis and have been found in sera. Relationship of cause and effect of these immunological findings is unclear, because immune complexes are found in many disease types. Although these autoantibodies may be associated with equine diseases, it is unlikely that they initiate arthritis in horses.³⁰ They may develop after exposure to type II collagen, after articular cartilage trauma, or with wear. Specific assays of synovial fluid for immunoglobulin

M-rheumatoid factor (a feature of rheumatoid arthritis), antibodies to heat-shock protein, and antinuclear antibodies (ANAs), a feature of SLE, reveal only modestly low levels of rheumatoid factor without correlation to disease and no ANAs.³¹

IMMUNE-MEDIATED ARTHRITIS

The presence of synovitis and immunoglobulin G complex deposition in the synovium of foals has been reported.³²⁻³⁴ This form of synovitis is called *immune-mediated arthritis* and may be associated with circulating immune complexes formed as a result of systemic disease.³² Using specific monoclonal antibody techniques, immune-mediated arthritis was diagnosed in a 6-week-old pony foal infected with equine herpesvirus-4.³³ Three horses were hyperimmunized with *Streptococcus* equine M protein vaccine and subsequently injected intraarticularly with purified streptococcal M protein. Severe suppurative synovitis developed, and synovial fluid nucleated cell counts were greater than 100,000 cells/mcL.³⁴ Eosinophils were prominent in the synovial fluid and synovial membrane in two horses.

A clinical syndrome of polysynovitis and vasculitis secondary to high circulating M protein (after streptococcal infection), or associated with *Rhodococcus equi* infections, is recognized and thought to be caused by immune-mediated arthritis. Seventeen (35%) of 48 foals with *R. equi* pneumonia infection had chronic active noninfectious arthritis. Pathogenesis involves immunocomplexes in the synovium. The hallmark of immune-mediated arthritis in foals is effusion in one or more joints but minimal lameness.³⁵ Synovitis often resolves in several weeks with or without treatment. Foals should be restricted to box rest, but no other specific treatment is necessary. Corticosteroids are contraindicated, because bacterial infection may be perpetuated.

REACTIVE SYNOVITIS

Reactive synovitis may occur after intraarticular injection of any product. Any intraarticular injection incites at least mild synovitis. The activated drug or a product in the solution may chemically induce reactive synovitis. Endotoxin contamination of multiple-dose vials or even single-dose products may cause reactive synovitis. In the case of a multiple-dose vial, a suspicion of endotoxin contamination should be high if more than one horse shows clinical signs within a short period. Horses are exquisitely sensitive to endotoxin, and concentrations above 0.125 ng per joint incite synovitis.³⁶ After intraarticular injection of methylprednisolone acetate, inflammatory cells surrounding vehicle crystals were identified in synovium 6 weeks later.³⁷ Reactive synovitis associated with methylprednisolone acetate may be most common in the distal interphalangeal joint. Although unusual, within a few hours after injection, horses can show severe lameness. Steroid arthropathy may be a form of reactive synovitis. The distal interphalangeal and tarsocrural joints appear most at risk to develop reactive arthritis after intraarticular injection of polysulfated glycosaminoglycans.³⁸

Reactive synovitis must be distinguished from early infectious arthritis. Distinguishing features of reactive

arthritis include early onset after injection (about 24 hours), synovial nucleated counts less than 30,000 cells/mL, and resolution of clinical signs within 1 to 3 days. Lameness ranges from mild to severe, and in some horses distinguishing reactive arthritis from infectious arthritis may be difficult, and prompt management with intraarticular lavage, systemic and local antimicrobial drug administration, and antiinflammatory therapy should be instituted. Culture and susceptibility testing should be performed if any suspicion exists that a bacterial infection is present, if synovitis does not resolve quickly, or in horses in which lameness persists.

Eosinophilic synovitis is rare and may represent an allergic reaction to an injected product, or to parasite migration, or could be truly idiopathic.^{34,39} Joint lavage to assist in removing foreign material, and the administration of NSAIDs and anthelmintic treatment are indicated.

Foreign bodies rarely may be present within a joint or tendon sheath and incite chronic reactive synovitis. Broken needles, plant or seed awns or thorns, and debris from nearby wounds can cause reactive synovitis. Radiological and ultrasonographic examinations can be helpful to identify the nature of the foreign material.⁴⁰ Cellulitis close to a joint may cause reactive synovitis that resolves with successful treatment of the primary infection.

TRAUMATIC SYNOVITIS

Primary traumatic synovitis is an early form of OA. Horses at risk are usually in active sports training. Lameness usually is managed by intraarticular and systemic medication. Early medical intervention and appropriate joint rest and physiotherapy are critical to prevent loss of glycosaminoglycan from articular cartilage and permanent joint wear. Early loss of articular cartilage proteoglycan is reversible with medication and joint rest. If training is continued, some horses will develop proliferative synovitis, chip fractures, intraarticular ligament injury, and OA. Intermittent hemarthrosis (see later) may be detected with primary traumatic synovitis, but often it indicates injury to subchondral bone, such as chip fracture or cartilage elevation.

PROLIFERATIVE (VILLONODULAR) SYNOVITIS

Chronic traumatic synovitis and continued exercise result in a painful thickening of the synovium, proliferative synovitis, particularly in areas of compression trauma.⁴¹⁻⁴⁵ The most common location is the dorsal fibrous pad (synovial pad) of the metacarpophalangeal joint, directly under the broad, flat common digital extensor tendon and joint capsule.⁴¹ At maximal extension and flexion, pad compression results in intrasynovial hemorrhage, granulation tissue formation, fibrosis, and mineralization. Diagnosis and management are discussed in Chapter 36.

Chronic proliferative synovitis is a frequent finding in the carpal and tarsocrural joints during arthroscopic

examination. Diffuse proliferative synovitis can be seen in horses that have had frequent intraarticular injections and have continued in exercise. Capsular fibrosis and loss of fine villous architecture occur. I do not recommend radical synovectomy, but removal of fibrotic tufts of capsule and synovium prone to pinching or demonstrating signs of internal hemorrhage and edema is warranted.

See Chapters 54 and 56 for a discussion of osteochondrosis.

IDIOPATHIC ARTHRITIS

Synovitis can occur without any known cause or associated trauma and can be truly idiopathic, although synovitis may be related to circulating toxins, including endotoxin, streptococcal cell wall, M protein, and viruses. In people, bacterial and viral deoxyribonucleic acid and bacterial peptidoglycans have been located in joints of patients with early rheumatoid and other noninfectious arthritides.^{46,47} In horses synovitis can be associated with vasculitis, such as that seen with equine viral arteritis.

HEMARTHROSIS

Bleeding into a joint (hemarthrosis) causes joint capsule distention, severe pain, and lameness.⁴⁸ Draining the blood from the joint usually results in rapid relief of clinical signs. The cause of hemorrhage may be trauma to proliferative hemorrhagic synovium, an intraarticular fracture, or tearing of an intraarticular ligament. Hemorrhage may occur on a single occasion or may be recurrent. Diagnosis of hemorrhage is simple, by arthrocentesis, but identification of the primary cause can be more difficult. In the absence of radiological abnormalities, exploratory arthroscopy is warranted in a horse with recurrent episodic severe lameness associated with hemarthrosis. Hemorrhage associated with proliferative synovitis may be managed successfully by subtotal synovectomy. (Editors' note: hemarthrosis appears to most commonly affect the antebrachicarpal and tarsocrural joints but rarely can involve other joints such as the middle carpal joint.)

LYME DISEASE

Although strictly speaking an infectious disease, Lyme disease is discussed in this section because it should be considered a differential diagnosis in tick-endemic areas in a horse with shifting limb lameness associated with synovitis in several joints.^{49,50} However, many clinically normal horses have antibody titers to *Borrelia burgdorferi*, and high titers are not synonymous with clinical disease.⁵¹ Authentic Lyme disease is poorly documented in the horse, and definitive diagnosis would require identification of substantially raised titers in paired serum samples. Tetracycline most effectively eliminated positive cultures and antibodies to *Borrelia* as compared with use of doxycycline or ceftiofur.⁵²

Chapter 67

Other Joint Conditions

Chris E. Kawcak

Several types of joint diseases are rare and have been presented only in case reports or small retrospective studies. This makes generalizations about these diseases difficult and searching for information a tedious process.

DISEASES OF SOFT TISSUES OF THE JOINT

Soft tissue structures serve to support the joint, and disease can result in abnormal stresses to the articular cartilage and hence chronic progression of articular cartilage degeneration and osteoarthritis (OA) (see Chapter 61). Preoperative diagnosis of some soft tissue injuries is difficult, often leaving the surgeon with little to do other than evaluate the injured area and debride fibrillated tissue during arthroscopic surgery. With the advent of newer diagnostic techniques such as magnetic resonance imaging (see Chapter 21) and increased use of ultrasonography (see Chapter 17), soft tissue injuries can be characterized better preoperatively.

Most soft tissues of joints, such as ligaments, menisci, and joint capsules, function to support joints. Joint ligaments maintain alignment of opposing and adjacent bones in joints. They form a connection between opposing bones (such as the tibia and femur in the stifle) and between adjacent bones in more complex joints (such as between the carpal bones). They function to maintain alignment and allow for movement of the joint. The meniscal cartilages function as cushions between the tibia and femur of the femorotibial joints. Proper material characteristics are necessary for maintenance of the joint environment. The joint capsule is also responsible for maintaining joint support and provides a barrier for synovial fluid. Because the capsule surrounds the entire joint, appropriate elasticity is needed to maintain joint flexibility (see Chapter 66).

Ligament Injuries

Joint ligament injury can be an incidental finding during surgery or a devastating cause of lameness. For instance, medial palmar intercarpal ligament damage can be an incidental finding during arthroscopic surgery and has been seen incidentally in necropsy specimens (see Figure 23-4 and Chapter 38).¹

Injury to cruciate ligaments and menisci of the stifle usually causes substantial pain (see Chapter 46), but cutting the cranial cruciate ligament in an attempt to create a model of OA did not lead to OA in horses. Therefore further destabilization of the joint beyond cruciate injury must usually occur, with possible damage to other soft tissue structures, including the joint capsule.

Collateral ligament injury caused by a bad step or laceration can result in subtle or severe lameness. I have seen low-grade lameness in a horse that had complete tearing

of the medial collateral ligament of the metatarsophalangeal joint (Figure 67-1). Laxity of the joint was detected by manipulation and stress radiographs. The joint was immobilized in a cast for 6 weeks, followed by use of a splint for an additional 6 weeks. Reinjury occurred after splint removal, and the joint was recast. After immobilization for 16 weeks the injury healed well enough for trail riding. Others have described collateral ligament abnormalities in the carpus and its close association with OA.²

Ligament injuries usually heal slowly, and gradual return to function is needed to strengthen the tissues. The consequences of collateral ligament injury depend on the severity of damage to the ligament, contamination in the joint, and damage to other structures in the joint and may be difficult to predict at the time of injury. Long-term instability may place abnormal stresses on the joint and lead to progressive OA. Cutting the lateral collateral and lateral collateral sesamoidean ligaments of the metacarpophalangeal joint resulted in lameness, increased joint circumference, decreased range of motion, and osteophyte formation in 8 weeks, resulting in OA.¹

Hygroma

A hygroma is an adventitious or acquired bursa on the dorsum of the carpus caused by trauma from falling, getting up and down, or hitting a fence or by chronically pawing and hitting the dorsum of the carpus.³⁻⁵ Nonpainful, fluctuant, uniform soft tissue swelling occurs on the dorsal aspect of the carpus. Pressure does not induce swelling in any associated joints or tendon sheaths. Range of motion of

Fig. 67-1 • A 3-year-old Paint gelding had acute swelling on the medial aspect of the metatarsophalangeal joint. A stress dorsoplantar radiographic image shows subluxation of the metatarsophalangeal joint caused by complete rupture of the medial collateral ligament (medial is to the left).

the carpus may be reduced, but lameness is unusual. Injection of radiodense contrast agent into the hygroma or ultrasonographic examination confirms its extraarticular position.

Spontaneous resolution of hygromas may occur, but treatment is often necessary. Drainage and injection of antiinflammatory agents has been used with varying success; in many horses repeated injection is necessary.^{4,5} I have seen spontaneous resolution after injection of a radiodense contrast agent. Injection of atropine (7 mg) may resolve the swelling. Owners should be warned that bandaging is an essential component of treatment and that long-term chronic thickening may occur.

Other treatments include incisional drainage; injection of irritants, such as iodine or Lugol's solution; and blistering,^{4,5} but contrast radiography should be performed to ensure that the hygroma is an isolated structure. Although preoperative contrast radiographs may show no communication between a hygroma and a joint or tendon sheath, one might exist in the form of a one-way valve from the joint into the mass.⁶ Treatment involving drainage of the mass with a Penrose drain and bandaging has been used successfully for recurrent hygromas. Drains usually are removed once drainage stops, 2 to 7 days after placement.⁷ Surgical excision can be performed in horses with chronic hygroma and is best accomplished if the fluid sac is left intact and dissected from the other tissues (see Chapter 38).⁸ Soft tissue and skin closure are routine, and a splint can be used to prevent flexion for better healing. Prognosis for resolution of hygroma is often good, although some degree of thickening usually persists.

Synovial Hernia

A synovial hernia is a defect in a joint capsule or tendon sheath through which the synovial membrane can protrude. The condition rarely causes lameness but is a cosmetic blemish (see Chapter 74). A well-defined, round, soft tissue mass can be palpated over a joint, and with palpation fluid often can be moved between the hernia and the underlying joint or tendon sheath (Figure 67-2). The hernia may disappear with joint flexion. Contrast agent injected into the hernial sac is detected in the underlying joint or tendon sheath, although a one-way valve may be present, limiting movement of contrast material. If the synovial hernia is of cosmetic concern, surgical excision can be performed, with a good prognosis for soundness provided no other joint diseases are present.⁹

Ganglion

A ganglion is a fluid-filled structure that connects to a joint or tendon sheath through a one-way tract from the joint into the mass.³ Unlike a synovial hernia, the mass lacks a synovial lining and often is filled with mucin. Ganglions are rare in the horse but common in people, and they have been reported around the stifle and the carpus.³ A ganglion adjacent to the fetlock was associated with lameness that was alleviated by regional analgesia and after surgical excision of the mass.¹⁰ However, communication with the digital flexor tendon sheath and joint was not demonstrable by ultrasonography. Demonstrating connection between a ganglion and an adjacent joint by injection of radiographic contrast agent into the mass may or may not be possible (see Chapter 74).⁷

Fig. 67-2 • A synovial hernia on the dorsum of a carpus.

Synovial Fistula

Synovial fistulae are communications between two synovial structures, usually a joint and tendon sheath. They have occurred between the antebrachio-carpal joint and the common digital extensor tendon; the middle carpal joint and the extensor carpi radialis tendon sheath or the common digital extensor tendon sheath; the proximal interphalangeal joint and long digital extensor tendon sheath; and the extensor carpi radialis tendon sheath and a carpal hygroma.^{6,11-13} Additional joint damage is often present in association with the fistula, causing lameness referable to the area.

Swelling in the joint and nearby tendon sheath occurs, and fluid is often movable between the structures (Figure 67-3). Radiology may reveal additional joint or tendon sheath damage, and contrast agent injected into one of the structures is visible in the other.¹¹

Occasionally a fistula can be seen during arthroscopic surgery, but closure of the fistula requires an arthrotomy. However, arthroscopic surgery for treatment of a primary problem, without repair of the fistula, has resulted in resolution of lameness, without resolution of the swelling. I do not close these fistulae unless a cosmetic effect is important, or if the swelling itself is impeding performance, or if medical therapy fails to alleviate lameness.

NEOPLASIA

Joint-associated tumors in horses are rare and consequently behave unpredictably, and relying on treatment information from other species is difficult. Soft tissue tumors in horses are vascular, fibrous, or synovial in origin. Benign

Fig. 67-3 • Dorsal view of a carpus with effusion of the antebrachicarpal joint and common digital extensor tendon sheath. A synovial fistula was seen during arthroscopic surgery.

vascular masses such as hemangiomas have been seen in carpal and digital flexor tendon sheaths of horses.³ The digital flexor tendon sheaths were distended with blood-stained fluid, but no associated lameness occurred, and surgical excision of the masses was curative.

Fibromas may occur as slow-growing masses near the tarsus, stifle, and distal radius. These masses are rarely erosive to associated bone. Complete surgical excision may be curative, but incomplete excision can result in recurrence.^{12,14} A fibroma on the proximal lateral aspect of the tarsus was incompletely resected, and over a 4-month period the mass regrew to larger than its original size.¹⁵

Villonodular (proliferative) synovitis is a common traumatic injury on the proximal dorsal aspect of the metacarpophalangeal joints of racehorses and is not a tumor (see Chapters 36 and 66). Keratinization of a villonodular synovitis was associated with severe lameness.¹⁶ It was suggested that this was a form of epidermal inclusion cyst, the result of inadvertent introduction of epidermal tissue into the joint after repeated arthrocentesis for previous infectious arthritis, resulting in a foreign body reaction. Surgical resection resulted in resolution of lameness. Pigmented

villonodular synovitis has occurred in the metatarsophalangeal and femoropatellar joints, resulting in chronic lameness in a mule.¹⁷

Synovial cell sarcomas have been identified in the antebrachium,¹⁵ a digital flexor tendon sheath,¹⁸ and the proximal interphalangeal joint associated with soft tissue swelling and variable lameness. The masses had infiltrated the soft tissues and caused localized inflammatory bone loss because of pressure. There may be recurrence after surgical excision.¹⁹ Chondrosarcomas are rare, but they have been described in a metacarpophalangeal joint²⁰ and the carpal region,²¹ associated with expansible radiolucent lesions. Osteosarcoma is also quite rare but has been described in the proximal aspect of the tibia and periarticular to the shoulder joint.²² The horse with the periarticular mass was successfully managed with excision.²² Osteosarcoma was described in the tarsus of a horse and involved the calcaneus and the proximal intertarsal joint.²³ Mast cell tumors have also been identified around joints as mineralized masses that are responsive to excision.²⁴ They do not appear to invade joint capsules in general. A secondary melanoma in a shoulder joint that caused severe lameness has been described.²⁵

A hemangiosarcoma occurred in the tarsal sheath, and surgical excision resulted in relief of lameness.²⁶ However, in a retrospective study of hemangiosarcoma in young horses, the investigators found masses in numerous joints that not only caused radiological evidence of pressure atrophy on surrounding bones but also were unresponsive to surgical excision.²⁷ A neonatal foal with unusual congenital hemangiosarcomas in numerous sites, including the fetlock and stifle joints, has been described.²⁸ The synovial fluid from those joints was hemorrhagic to orange in appearance.

OSTEOCHONDROMATOSIS

Synovial chondromatosis and osteochondromatosis are conditions involving pieces of uncalcified and calcified hyaline cartilage, respectively. Synovial chondromatosis is a disease in which hyaline cartilage can occur in the joint in pedunculated form, within the synovial membrane, or free within the joint. Osteochondromatosis results when endochondral ossification of the mass occurs, often making it difficult to differentiate from osteochondral fragmentation. Osteochondromatosis has occurred in the femorotibial joint.^{3,29} Secondary osteochondromatosis also occurs within joints with OA. The condition is often painful in people, and surgical removal is indicated. Osteochondromatosis has occurred incidentally in horses without lameness.

Chapter 68

Pathophysiology of Tendon Injury

Roger K.W. Smith

FUNCTIONAL ANATOMY OF EQUINE TENDONS AND LIGAMENTS

Tendons passively *transfer force* generated by muscle to bony attachments on the opposite side of a joint, or joints, to provide movement. In contrast the function of a ligament is to resist distraction of its two bony attachments (e.g., collateral ligaments and suspensory ligament [SL]). Although this function is true for most tendons and ligaments, the horse has evolved its digital flexor tendons and SL to exhibit additional functions. These tendons and ligaments, situated on the palmar distal aspect of the equine limb ([Figure 68-1](#)), receive large weight-bearing loads because of the hyperextended metacarpophalangeal and metatarsophalangeal joints. As a result the tendons and ligaments on the palmar aspect of the distal limb act to *support* the metacarpophalangeal and metatarsophalangeal joint during normal weight bearing.

In addition, the equine digital flexor tendons exhibit considerable elasticity that is used to *store energy* for energy-efficient locomotion.¹ In the case of the superficial digital flexor tendon (SDFT), its muscle is highly pennate (the muscle fibers are arranged at an oblique angle to the line of pull of the muscle, which maximizes power and minimizes contraction distance) and is unable to contract by more than a few millimeters.² Therefore the action of the muscle, together with its accessory ligament, is largely passive to fix the origin of the SDFT in space. Although the muscle contracts only a short distance, its action, together with the tendon elasticity, also provides *shock absorption*.² The gait of a horse at speed can be compared with a weight (the horse's body) bouncing up and down on elastic springs (the digital flexor tendons and SL) in a similar fashion to a pogo stick's bouncing.³ This arrangement allows horses to reach and maintain high speeds while minimizing energy expenditure (see Chapter 26).

FUNCTIONAL CHARACTERISTICS

Biomechanical Properties

When a tendon is loaded, it stretches. The relationship between the force and the elongation defines the structural

properties of the specific tendon or ligament. Because these properties depend on the size of the structure, comparison between tendons and ligaments is better made from the material properties of the tissue, which are determined by plotting the force per unit area (stress) against the percentage elongation (strain). A stylized example of such a stress-strain curve for tendon is shown in [Figure 68-1](#). The curve has the following four regions:

1. The toe region, where stretch to the tendon is non-linear. This is associated with the elimination of the undulating pattern of the collagen fibrils (known as *crimp*; see the following discussion).
2. Linear deformation—the area of the curve from which the modulus of elasticity, which characterizes the elasticity of the tendon, is determined. The mechanism for this elongation is unclear, but it involves elongation of the collagenous network, with the majority of the elongation arising from the movement of tendon fascicles relative to one another.⁴
3. The yield region, in which irreversible lengthening of the tendon occurs at these strains, possibly arising from covalent cross-link rupture and slippage of collagen fibrils.
4. Rupture, in which the stress falls quickly to zero as the collagen cross-links or fibrils sequentially rupture.

Biomechanical Parameters

A number of simple biomechanical parameters, which are derived from their structural and material properties, can be ascribed to tendons. Some of the values of these parameters for the palmar supporting structures of the distal limb are shown in [Table 68-1](#). A parameter not frequently calculated, but probably more relevant to the in vivo situation, is the force or stress at the yield point, after which irreversible damage is occurring.

Structural Properties

The ultimate tensile strength is the load at which the tendon breaks. The SDFT receives in excess of 1 metric ton at maximum weight bearing in vivo and breaks at 1.2 to 2 metric tons when tested ex vivo in a materials testing apparatus. Within any population of horses, large variation occurs in the ultimate tensile force, with up to a twofold difference between the weakest and strongest tendons.⁵

Stiffness is the load required to extend a tendon by a unit length and is the parameter that has to be optimized to the weight of the horse for the tendon to act efficiently as a spring.

Material Properties

One property is the ultimate tensile stress. As the SDFT is only about 1 cm² in cross-sectional area, the ultimate tensile stress (force at failure per unit area) in the horse is close to 100 MPa, which is at the upper limit of previously documented figures for other species (45 to 125 MPa).^{6,7} The large variation seen for the structural strength also exists for ultimate tensile stress, indicating that the variation does not result merely from differences in cross-sectional area. It is hypothesized that the horses with weaker tendons are more prone to tendon injury. Another property is the modulus of elasticity or stiffness (E), which is a constant determined from the ratio of stress to strain for the linear part of the stress-strain curve. The modulus of elasticity for the SDFT is about 1000 MPa. Frequently it is correlated with ultimate tensile stress, so that the stronger the tendon, the stiffer it is.

The property, ultimate tensile strain, is the percentage extension of the tendon at its breaking point. In vitro testing of equine digital flexor tendons indicates that they usually

Fig. 68-1 • Simplified stress-strain curve for tendon. 1, Toe region; 2, linear deformation; 3, yield; 4, rupture. (From Goodship AE, Birch HL, Wilson AM: The pathobiology and repair of tendon and ligament injury, *Vet Clin North Am Equine Pract* 10:323, 1994.)

extend by 10% to 12% of the original length before they rupture, although values of up to 20% have been reported.⁸ However, the ultimate tensile strain reflects only the final strain before rupture and includes that yield portion of the stress-strain curve that represents irreversible damage to the tendon tissue (see Figure 68-1). In addition, the ultimate tensile strain is not constant along the length of the SDFT in vitro⁹; the highest ultimate tensile strain occurs in the metacarpal region (the region most frequently injured).

In vivo, the normal strains in the digital flexor tendons (in ponies) are about 2% to 4% at the walk and 4% to 6% at the trot.¹⁰ At the gallop in Thoroughbreds (TBs), maximum strains in the metacarpal region of the SDFT can reach 16%.¹¹ Such strains are far greater than usually expected in tendons from most species and reflect the highly specialized nature of the equine digital flexor tendon. If these high strains are truly representative of the strains within the tendon, they indicate that equine tendon is operating at or close to its ultimate tensile strain. This suggests little tolerance in the system, which explains the high incidence of injury in this structure. However, some caution in the interpretation of in vitro measurements is necessary, because studies have shown different results obtained between in vivo and in vitro tests.¹⁰

Hysteresis

Hysteresis refers to the energy loss between the loading and unloading cycles of tendon (Figure 68-2), determined from the area between these two curves. Hysteresis is usually about 5% in equine tendons.¹² Some of this energy is responsible for the rise in temperature within the tendon core associated with repeated loading (as in an exercising horse), which has been suggested as a causative factor in equine superficial digital flexor tendonitis¹³ (see the following discussion).

Classification of Tendons and the Relationship to Function

Research has demonstrated that tendons possess different properties depending on function.^{8,14} The tendons in the

horse, like those in people, can be divided into two broad categories: those with the primary function of withstanding the weight of the horse (weight-bearing tendons) and those with the primary function of flexing, extending, or rotating joints (positional tendons). Weight-bearing tendons, such as the equine digital flexor tendons, are more elastic than positional tendons (e.g., the equine digital extensor tendons), which reflects the function of the digital flexor tendons as elastic energy stores. Positional tendons require stiffness for accurate positioning of the limb or digit. Human finger tendons are stiff for such a purpose, and although equine digital extensor tendons are not required for accurate placement of the digit, they nevertheless resemble this category of positional tendons.¹⁴ These differences in biomechanical properties are reflected in the anatomical features of the tendons.

ANATOMICAL STRUCTURE

Morphology of Tendons

Tendon is composed of a hierarchical structure of subunits. To the naked eye, in cross-section the tendon substance is divided into a number of fascicles, which are in turn composed of ever decreasingly sized subunits: fibers and then fibrils.

The fascicles are held together by the loose connective tissue, the endotendon, which is confluent with the outside of the tendon, the epitendon. The endotendon contains vascular and neural elements. In regions where the tendons are not surrounded by a tendon sheath, a thick fibrous layer, the paratendon, further surrounds the tendon.

Crimp

In longitudinal section, under a light microscope, the collagen fibers in tendon have a wavy appearance known as *crimp*. This pattern is responsible in part for the elasticity of the tendon, and it is eliminated in the toe region of the stress-strain curve when the mechanical behavior of the tendon is nonlinear. A generalized reduction in the crimp angle occurs with aging, with a differentially greater reduction in the central fibers.^{15,16} As a tendon stretches, the central fibers straighten first and therefore receive

differentially greater load than the peripheral fibers, which may explain the site of pathological damage in those horses with centrally positioned core lesions. The reason for lesions situated peripherally in a tendon is less clear, unless these are also focal regions of the tendons that have developed atypically straightened fibers. Lesions involving the entire cross-section of the tendon represent a more generalized disruption of the tendon matrix.

Collagen Fibril Diameter

The collagen fibrils are composed of many triple helical collagen molecules arranged in a quarter stagger, which gives a characteristic banding pattern on electron microscopy. These collagen molecules are synthesized by the tenocytes within the tendon, where early events of collagen fibril formation are associated with cellular projections (fibripositors),^{17,18} which are thought to be responsible for laying down the template of linearly arranged collagen fibrils during development. Subsequent enlargement of the collagen fibrils occurs extracellularly, by covalent intermolecular cross-linking (see the following discussion). Fusion of adjacent fibrils is responsible for the increasing size of collagen fibrils with age.^{19,20} Soon after birth, foals develop the characteristic of a bimodal or trimodal pattern of fibril diameters in the SDFT, in which the fibrils can be grouped into two or three populations (small [40 nm], medium [120 nm], and large [>200 nm]), whereas positional tendons tend to have a more consistent unimodal distribution of larger diameter fibrils in adults.²¹

Associated Structures

Blood Supply

Tendons obtain nutrients from two primary processes: perfusion and diffusion. Diffusion of nutrients from compartments other than blood occurs predominantly where the tendon is enclosed in a sheath, the synovial fluid playing an important role in tendon nutrition.

The principal blood supply in tendon arises from three sources: proximally, the musculotendonous junction; distally, the osseous insertion; and between these two, the tendon is supplied by intratendonous and extratendonous vessels. The extratendonous supply arises from the paratendon in extrasynovial tendon and from mesotendon attachments within synovial tendon sheaths (such as the vinculum between the fetlock annular ligament and the SDFT). The predominance of either source in the midtendon region depends on the species and the tendon. In the equine SDFT, two major parallel vessels run longitudinally in the lateral and medial borders of the midmetacarpal tendon, accompanied by an extensive anastomosing network of vessels.²² These vessels anastomose with paratendon blood vessels, although removal of the paratendon blood supply in the horse failed to produce gross pathological damage. However, ligation of the intratendonous supply in the midmetacarpal region produced ischemic pathological damage, demonstrating the importance of the intratendonous supply. The deep digital flexor tendon (DDFT) also has an anastomosing vascular network, except for its dorsal aspect as it passes over the metacarpophalangeal joint, where it has a more fibrocartilaginous phenotype to resist the compressive forces in this region.²³

Fig. 68-3 • Absolute blood flow in equine digital flexor tendons derived from ^{133}Xe clearance half-times. Numbers above the columns indicate the numbers of tendons evaluated. DDFT, Deep digital flexor tendon; E, exercised; MC, metacarpal region; MCP, metacarpophalangeal region; NE, not exercised; SDFT, superficial digital flexor tendon; SDFTci, contralateral "normal" SDFT; SDFTi, superficial digital flexor tendonitis. (From Jones AJ: Normal and diseased equine digital flexor tendon: blood flow, biochemical and serological studies, PhD thesis, 1993, University of London.)

Tendon has been shown to have a good blood supply based on a number of techniques, usually involving clearance measurements of various radionuclides injected intra-tendonously (most commonly ^{133}Xe and ^{24}Na). The SDFT appears to have good blood supply similar to that of resting skeletal muscle, although findings have been inconsistent among studies and among animals on successive measurements. The large variation in the blood flow under different circumstances may indicate that external factors, as yet undefined, influence blood flow on a day-to-day basis.

Differences in blood flow between the SDFT and DDFT are affected by age, exercise, and injury (Figure 68-3).²⁴ The SDFT has a slightly higher blood flow than the DDFT, which reflects its good vascular anatomy (see the previous discussion). However, studies showed similar functional blood flow throughout the metacarpal region of the SDFT, although histologically and microangiographically the middle and distal regions were less well vascularized.²⁵ However, not surprisingly, the DDFT in the metacarpophalangeal joint region has a significantly lower blood flow, associated with its fibrocartilaginous phenotype, with few blood vessels because of the high compressive forces in this region, which would limit any blood flow.

The blood flow appears to be considerably higher in foals than in adult horses, with a gradual decline in blood flow to the adult level by 3 years of age.

Exercise induces an increase in blood flow (about 200%), although this increase is delayed in animals not previously trained. The tendon blood supply therefore appears to exhibit a fitness memory.

Injury provokes a considerable increase in blood flow (>300%), which occurs in both clinically affected and clinically unaffected limbs, consistent with the bilateral nature of tendonitis in the horse, even though one limb is more severely affected than the other. Other measurements carried out in injured tendons have yielded variable results,

which have been interpreted as representing the coexistence of fibrous tissue with low blood flow and hyperemic areas of acutely inflamed tendon.

Cellular Components

Although the biomechanical characteristics of tendon are determined by the composition and organization of the extracellular matrix, tenocytes are essential for the formation and maintenance of tendon tissue. At least three different populations of tenocytes are identifiable within the fascicles of normal equine tendon and ligament^{8,26} (Figure 68-4):

- Type I: Cells with thin, spindle-shaped nuclei
- Type II: Groups of cells with more rounded, thick, cigar-shaped nuclei
- Type III: Cartilage-like cells with round nuclei and visible nucleoli

The proportion of these cells varies between tendons and ligaments, with tendon site, and with age.²⁷ Young tendon has considerably larger numbers of type II cells arranged between collagen bundles. With aging, type I cells predominate, whereas in the areas subjected to compressive forces, type III cells can be identified.

The activity of these different cell types is unknown. The different cell types identifiable histologically may represent different cell lines or different states of extracellular matrix production. A reasonable assumption is to suppose that type II and III cells are metabolically more active and are responsible for maintaining the tendon extracellular matrix, although the metabolic activity of the type I cells cannot be discounted. There appear to be phenotypic differences between cells recovered from different tendons maintained in vitro, which reflect the matrix of the tendon from which they were derived. Tenocytes recovered from flexor tendons exhibit high cartilage oligomeric matrix protein (COMP) synthesis (see later), whereas those

recovered from extensor tendons produce much less COMP but are metabolically more active.²⁸

Ligament has a much higher cell population, with a predominance of type II cells arranged in columns. In the SDFT of the horse, which has greater numbers of cells during growth, total tendon cell numbers remain relatively constant after skeletal maturity. However, acellular areas

develop, especially in the center of the SDFT in the metacarpal region, although the degree of acellularity is not particularly related to age.²⁹ More active, type II cells can be found surrounding the fibrils in these regions, as well as chondroid metaplasia. Other areas, typified by the DDFT in the metacarpophalangeal region, also have acellular regions associated with a fibrocartilaginous phenotype

(type III cells and cartilage-like matrix) as a result of concurrent compressive forces as the tendon wraps around the metacarpophalangeal joint. Other cells are associated with the tendon, namely the paratendon, epitendon, and endotendon fibroblasts and the synovial-like cells of the epitendon within the tendon sheaths. These cell populations may also play important roles in maintaining tendon tissue, especially because the endotendon harbors certain growth factors, such as transforming growth factor- β (TGF- β) (Figure 68-5).³⁰ Furthermore, as the endotendon contains the vasculature, it is also likely to contain a source of pluripotential cells, which may be responsible for intrinsic healing mechanisms,^{31,32} although pluripotentiality in cells derived from tendon has showed inferior capabilities compared with cells recovered from a more conventional source, the bone marrow.³³

The regulation of tenocyte metabolism still is not understood fully but probably relies on a combination of mechanical and cytokine stimuli. Tenocytes have been shown to sense and react rapidly to mechanical stimuli *in vitro*.³⁴ However, equine tenocytes in culture require the addition of a suitable growth factor to initiate a synthetic response to load.²⁸ The use of confocal microscopy has provided an insight into the relationship among tenocytes. Staining with a membrane dye revealed extensive cytoplasmic extensions from tenocytes, which form a complex meshwork around the collagen bundles. Gap junctions exist between cytoplasmic extensions, which would provide an ideal arrangement for the coordinated biosynthetic reactions to mechanical stimuli.³⁵

Of the multitude of growth factors having effects on connective tissues, TGF- β and insulin-like growth factor 1 have been investigated the most in equine tendon.^{30,36,37} The synthesis and distribution of TGF- β isoforms in equine digital flexor tendon vary with age. The highest levels are observed in young equine digital flexor tendon, especially within the endotendon.³⁰ Levels decline after skeletal maturity, especially in the tendon fascicles themselves, and this may result in a relative lack of tenocyte synthetic activity after skeletal maturity. However, it is not yet clear which are the most fundamental growth factors in equine

tendons and how the growth factor milieu acts to cause tendon matrix synthesis and repair.

Molecular Composition of Tendon Matrix

Tendons are composed predominantly of extracellular matrix, within which is a wide array of proteins, organized and interacting to produce the mechanical properties of tendon. The tendon extracellular matrix is composed predominantly of water (about 65% wet weight), collagen (about 30% wet weight), and noncollagenous glycoproteins (about 5% wet weight).

Collagen

About 80% of the dry weight of the tendon is collagen, of which the predominant collagen type is type I (>95%).⁸ Type III collagen is present in the endotendon and increases as the horse ages. Type II (the collagen of articular cartilage) is likely to occur at the same sites in the horse as described in other species—namely, tendon insertions and where tendons develop fibrocartilage-like tissue associated with a change in the direction of pull around bony prominences (e.g., at the metacarpophalangeal joint).

Collagen fibrils are strong, but the bonds formed between these fibrils and the higher order subunits are more likely to determine the strength of the tissue. The major covalent cross-link of type I collagen in tendon is between hydroxylysine and lysine residues.³⁸ Lysine and hydroxylysine are converted to the respective aldehydes by the action of the enzyme lysyl oxidase, which is inhibited by β -aminopropionitrile fumarate, a chemical that has been used in the treatment of equine tendon injuries. These lysine and hydroxylysine aldehydes then can form a number of different types of cross-links: reducible (e.g., dihydroxylysinonorleucine and hydroxylysinonorleucine) or nonreducible (hydroxylysylpyridinoline). The reducible cross-links become reduced with age so that at maturity their level is less than 10% of the level in the foal.³⁹

Noncovalent cross-links (electrostatic in nature) are provided by the proteoglycans and other glycoproteins, especially the small proteoglycan decorin, which coats the collagen fibril. Although individually these cross-links are less strong than the covalent cross-links, the high number and involvement in the higher order organization of the collagen network make them potentially major determinants of tendon mechanical properties.

Noncollagenous Glycoproteins

Cartilage Oligomeric Matrix Protein

COMP is a large molecule consisting of five subunits, bound via disulfide bonds at their N-termini to form a five-armed protein, with a bouquet of arms with globular C-terminal domains that can interact with other matrix components (Figure 68-6).^{40,41} Although initially thought to be restricted in distribution to cartilage, COMP subsequently was found largely in tissues whose function primarily is to resist load. Thus COMP is found in significant amounts in tendon, ligament, cartilage, intervertebral disk, and meniscus. In equine digital flexor tendons COMP shows large variation with site and age.⁴² Levels are low at birth and in the digital extensor tendon at all ages but accumulate within the digital flexors rapidly with weight bearing. Levels peak in the metacarpal region of the SDFT (at about 3% dry weight of tendon) at skeletal maturity and

Fig. 68-7 • The variation of cartilage oligomeric matrix protein levels with age in the metacarpal region of the superficial digital flexor tendon. (Modified from Smith RK, Zunino L, Webbon PM, et al: The distribution of cartilage oligomeric matrix protein [COMP] in tendon and its variation with tendon site, age and load, *Matrix Biol* 16:255, 1997.)

subsequently decline (Figure 68-7). Levels peak at a lower level in the metacarpophalangeal regions and in the DDFT but are maintained in the former.

The function of COMP has not yet been elucidated completely, but COMP is known to bind fibrillar collagens (I, II, and IX),^{43,44} and a mutation in the human COMP gene is responsible for pseudoachondroplasia, characterized by lax tendons and ligaments, short stature, and early-onset osteoarthritis.^{45,46} Although COMP may have a structural role, present research data suggest that it also may act to bring collagen molecules together to form fibrils, and it may assist in the organization of the collagen network.⁴⁷ This role may explain the decline in COMP levels after skeletal maturity in the metacarpal region, because the collagen matrix has been formed and limited remodeling occurs in an adult. In the equine SDFT, a significant correlation has been shown between ultimate tensile stress and COMP levels at skeletal maturity.⁴⁸ Thus high levels of COMP during development potentially enable the formation of a high-quality tendon matrix.

Proteoglycans

Proteoglycans are a group of molecules that possess a protein core and a side chain of sugars (glycosaminoglycans, or GAGs). The sugar side chains are highly variable in type and length so that great diversity exists even within a given tissue. Work on a variety of soft tissues, especially articular cartilage, has demonstrated a large number of different proteoglycans that are vital to maintaining the structural integrity of the tissue by playing structural roles or by regulating the metabolism of the tissue.

Proteoglycans are largely divided into two broad categories, the large and small proteoglycans. The large proteoglycans are exemplified by the major proteoglycan of cartilage, aggrecan, and the fibroblast-derived large proteoglycan, versican. These molecules possess a large number of GAG side chains, and some can form aggregates with hyaluronic acid. With the repulsion of the negatively charged GAG chains, this molecule has a bottle-brush shape and can trap large quantities of water. The swelling potential for this molecule, when restrained by the collagen network of cartilage, produces a structural matrix ideally suited to resisting compression. In tendon, areas subjected to compressive forces develop a matrix rich in these large proteoglycans, such as in the DDFT and SDFT in the metacarpophalangeal region.

The small proteoglycans such as decorin, biglycan, fibromodulin, and lumican usually have only one or two GAG side chains. Many of these proteoglycans have wide tissue distribution and both structural and regulatory roles. A number of these proteoglycans bind to other members of the extracellular matrix. Thus decorin, the most common proteoglycan in tensional tendon (e.g., metacarpal region of the digital flexor tendons), has been shown to bind to fibrils of type I collagen.⁴⁹ Decorin is thought to be responsible for regulating collagen fibril diameter and, together with the other small proteoglycans, may be responsible for providing electrostatic cross-links between fibrils, thus being also an important determinant of tendon strength. Targeted disruption of the genes for some of these small proteoglycans has confirmed a suggested role in maintaining tissue structural integrity. Deleting or knocking out the decorin gene results in variably sized collagen fibrils and poor mechanical strength in skin,⁵⁰ whereas targeted disruption of the fibromodulin gene causes altered collagen fibril morphology and reduced mechanical strength in tendon.⁵¹

Other Noncollagenous Glycoproteins

A number of other noncollagenous glycoproteins have been described in tendon, including elastin (not thought to be important for tendon elasticity in the horse),³⁹ fibronectin (which is up-regulated after injury), thrombospondin-4, PRELP (proline arginine-rich end leucine-rich repeat protein), and tenascin-C. However, the functions of these, and others that have yet to be characterized, have not been determined fully.

Types of Tendon Injury

Tendons can withstand intrinsic (overstrain) or extrinsic (percutaneous) injury or displacement. The most common injury in the horse is the intrinsic injury of the SDFT in the metacarpal region. Epidemiological data have indicated a frequency of 24% in National Hunt horses in

TABLE 68-2

<i>Studies Aimed at Investigating the Effect of Exercise of Equine Digital Flexor Tendons</i>						
POPULATION	STUDY NAME	AGE OF HORSE AT ONSET OF EXERCISE	DURATION OF EXERCISE	NATURE OF EXERCISE	AGE AT ANALYSIS	REFERENCES FOR PROTOCOL

training, rising to as high as 40% in some yards.^{52,53} Much of our understanding of tendon physiology (as described previously) and pathogenesis relates to the SDFT. Insertional injuries, although common in the human athlete, are rarer in the horse and more commonly are seen associated with the SL rather than the SDFT.

Clinical superficial digital flexor tendonopathy* varies in severity from individual fibril or fiber slippage to individual fibril or fiber rupture and ultimately to complete rupture of tendon with progressive involvement of more groups of fibers and fascicles. Although some overstrain injuries can be caused by simple overload of the tendon, clinical tendonopathy in many mature horses is believed to be preceded by subclinical degeneration of the tendon matrix. This is based on a number of observations. First, postmortem examination of tendons of horses euthanized for reasons other than tendonopathy revealed low-grade

pathological damage ranging from acellular areas, chondroid metaplasia, and cyst formation.^{29,54} Second, tendonopathy is frequently a bilateral disease, although one limb is more severely affected than the other. Although bilateral changes sometimes can be difficult to identify clinically, ultrasonography often confirms some degree of bilateral involvement.⁵² Third, research has identified a number of changes that occur within tendons, associated with aging and exercise, that are believed to be the major drivers of tendon degeneration that precedes clinical injury.

Mechanisms of Tendon Injury: Effect of Aging and Exercise

Various controlled exercise studies in adult and young horses (Table 68-2) have provided considerable information on the effect of exercise on normal equine tendons. In none of these studies was there any indication of clinical tendonopathy induced by the exercise protocols.

Regional differences in collagen fibril diameter have been seen in long-term exercised older horses, but not in short-term exercised or younger horses.⁵⁵ Within the central region of the SDFT there was a higher proportion of smaller fibrils in comparison with controls (Figure 68-8).

*Editors' note: The terms *tendonopathy* and *tendonitis* are used in this chapter, often synonymously. Most horses with injury of a digital flexor tendon have clinical signs such as heat, pain, and swelling, and as such the term *tendonitis* would generally apply. However, in some a lack of clinical signs and histological changes associated with inflammation may be most consistent with chronic degeneration of a digital flexor tendon; thus, the term *tendonopathy* may apply.

Fig. 68-9 • A, Transverse section of the superficial digital flexor tendon from the midmetacarpal region, showing asymptomatic central discoloration observed in some tendons at postmortem examination. **B** and **C**, Note the abnormalities demonstrated when the tendon is examined by ultrasonography in a water bath. The central hypoechoic region and increase in the tendon cross-sectional area in the transverse scans (**B**) and the central disruption of the fiber alignment pattern in the longitudinal view (**C**) resemble the changes observed with ultrasonography in clinical tendonitis. (From Goodship AE, Birch HL: Exercise effects on the skeletal tissues. In Back W, Clayton H, eds: *Equine locomotion*, London, 2001, Saunders.)

The higher proportion of small fibrils did not correlate with new collagen formation and thus may result from disassembly of the larger-diameter fibrils, rather than the formation of new collagen, which would indicate an adaptive response. Furthermore, the reduction in crimp pattern seen with aging was accelerated by the exercise protocols in adult horses.⁵⁶

Changes in molecular composition also occurred in long-term exercise studies, with a reduction in GAG content and an accelerated loss of COMP in the center of the tendon.⁵⁷⁻⁵⁹ In contrast, molecular analysis of tendons recovered post mortem with central discoloration but no previous diagnosis of superficial digital flexor tendonitis demonstrated an increase in type III collagen and GAG.⁶⁰ Because these tendons were enlarged substantially and had central hypoechoic lesions when examined by ultrasonography in vitro (Figure 68-9), these molecular changes probably reflect a reparative response rather than a degenerative change associated with aging and exercise.

In young growing horses, removal of load from tendon results in a lack of the normal COMP accumulation in tendon with growth, whereas removal of load after COMP

has accumulated does not alter its levels in the tendon. Data have shown an association between COMP levels and tendon strength at skeletal maturity,⁴⁸ so too little exercise may inhibit the ability of the tendon to develop quality tendon matrix. However, exercise studies during skeletal development indicated that tendons are more easily damaged if the exercise level is too high.⁶¹

These controlled exercise studies suggest that exercise accelerates a degenerative change that occurs inevitably with aging. Thus the research data suggest that after skeletal maturity a tendon has limited ability to adapt. Instead, cumulative fatigue damage weakens the tendon matrix and allows the initiation of clinical tendonitis when loading overcomes the resistive strength of the tendon, and the tissue tears. In support of this hypothesis, epidemiological studies documented a strong association of age and exercise with the incidence of tendon injury in both horses and people.^{53,62,63}

Further confirmation of cellular activity during growth, but not after skeletal maturity, has been provided by studies of matrix turnover and gene expression. The turnover of collagen was determined for experimental animals, but not

for the horse. In experimental animals, collagen turnover was high in neonates and growing animals, but it declined to low levels in adults.^{64,65} In bovine digital flexor tendons, matrix gene expression, as determined by in situ hybridization, was easily detectable in young, growing calves, but no gene activity was present in the metacarpal region in adults.⁶⁵ Interestingly, gene activity persisted in the metacarpophalangeal region, which may explain the relative resistance to injury of this region, because of its capability to remodel microdamage. In support of this hypothesis, COMP levels in this region of the equine SDFT and DDFT do not decline after skeletal maturity. The absence of synthetic activity in the metacarpal region appears to arise from a number of mechanisms. Research has shown that flexor tenocytes recovered from older tendons have reduced innate responsiveness²⁸ as well as having reduced levels of anabolic growth factors in the matrix, which act synergistically to elaborate an adaptive response. In studies investigating TGF- β in equine tendons, young equine tendon had high levels, but amounts declined after skeletal maturity.³⁰ Furthermore, there are reduced cell numbers in old tendon, and cells show no ability to increase with exercise,²⁷ reducing the cellular capacity for a response. Gap junction communication, evident in young tendon, through which a synthetic response can be coordinated, is dramatically reduced in older tendon.⁶⁶

In contrast, young growing tendon does appear to be sensitive to the effects of loading and exercise. The adaptive response of a growing animal may not be constant, and research data suggest that any response may be most pronounced early in life and may decline with growth. The level and amount of work necessary to induce this response are unknown, although, by analogy with bone remodeling in response to load, high strain rates may be the most effective. In support of this hypothesis, epidemiological studies indicated that horses are less prone to metacarpal fracture when they begin training earlier.⁶⁷ However, as with other skeletal tissue development, such as cartilage, it is hypothesized that a window of opportunity may be exploited to optimize conditioning of tendons for athletic performance (Figure 68-10). The large variation seen in the mechanical properties within a population could be accounted for by variations in tendon development or in rate of accumulation of microdamage, both caused by environmental factors, or it could be genetically determined. Although genetic factors have been linked to Achilles tendonitis in people,⁶⁸⁻⁷⁰ no such genetic determinants have yet been identified in horses, although one study gave a heritability coefficient for SDFT tendonopathy of 0.17.⁷¹ Such genetic factors could act by provoking the development of a less competent matrix or giving rise to a poor conformation that may predispose to tendonitis.⁷² However, the relative contributions of genetics and environment are so closely entwined that it is difficult to apportion causation specifically between the two.

Hypothesized Mechanisms of Tendon Degeneration

Mechanical Influences

Sudden overextension of the metacarpophalangeal joint may cause mechanical disruption of the digital flexor tendons. Although this may be the mechanism of certain tendon injuries, such as deep digital flexor tendonitis, direct

Fig. 68-10 • Hypothesized schematic representation of the adaptive response and injury risk for growing (immature) and adult (>2 years of age) equine digital flexor tendons. (Modified from Goodship AE, Birch HL: Exercise effects on the skeletal tissues. In Back W, Clayton H, eds: *Equine locomotion*, London, 2001, Saunders.)

low-grade mechanical forces, such as experienced under maximal loading, could be responsible for the cumulative fatigue microdamage of the tendon matrix. Subsequent clinical tendonitis is initiated by similar, or sudden supra-maximal, loading after the accumulation of microdamage.

Physical Influences: Exercise-Induced Hyperthermia

Because of the hysteresis loop, when a tendon is loaded and unloaded, a loss of stored energy as heat results in temperature increases within the equine digital flexor tendons. Thermocouples have been placed inside the SDFT, and these have recorded temperatures of up to 45° C during periods of galloping.¹³ Such temperatures are used to kill neoplastic cells therapeutically, so it was hypothesized that these temperatures would interfere with tenocyte metabolism and possibly destroy the cells. However, in vitro experiments have shown that tenocytes are much more resistant to these temperature increases in comparison with other fibroblast-like cells.⁷³ However, these experiments were performed on tenocytes in suspension culture, and more recent experiments in two-dimensional culture have suggested that such temperature rises can adversely influence gap junction communication between cells.⁷⁴ It is certainly possible that although the cells remain viable with such temperature increases, hyperemia may still adversely influence tendon matrix quality. An alteration in the normal balance between synthesis and resorption activity of tenocytes or a direct denaturing effect on tendon extracellular matrix may occur.

Vascular Theories

Blood flow through tendon is a complex issue, and its relevance to clinical injury is still unsubstantiated. Under maximal loading, blood flow is limited or abolished within the tendon because of the compressive forces generated by the lengthening of the tendon, and this may give rise to relative hypoxia. Indeed, color flow Doppler ultrasonography of equine tendons shows no detectable flow when a

horse is standing still, and even flow in the blood vessels of the distal aspect of the limb is sluggish until the horse moves. With injury, an increase in blood flow can be detected using Doppler ultrasonography, but only when the weight-bearing load is removed from the limb when it is raised off the ground. Some areas of equine digital flexor tendons are relatively poorly perfused (e.g., the dorsal portion of the DDFT in the metacarpophalangeal joint region), and this level (but not just the dorsal surface) is a site predisposed to deep digital flexor tendonitis. However, this area also shows histological adaptation to the relatively ischemic environment, with fewer cells and increased amounts of the compression-resisting extracellular matrix components. Furthermore, the tendon may receive some of its nutrition at this site by diffusion from the digital flexor tendon sheath synovial fluid. Similar alterations in the extracellular matrix composition are seen at the corresponding positions in the SDFT, and one could assume that the forces on this tendon would be similar to those of the DDFT at the same site. Therefore a reduced blood flow would also be expected at this level, and yet clinically this region is invariably spared injury in all but the most severe tendonitis.

Equine tendon cells do rely at least in part on oxidative metabolism, although blocking aerobic metabolism does not prevent normal cell proliferation.⁷⁵ Based on studies in other species, tenocytes may be more resistant to hypoxia than other, similar fibroblast-like cells.

Laser Doppler flowmetry has suggested that a change in blood supply is not the initiating cause in human Achilles tendonitis,⁷⁶ in contrast to the previously proposed hypoxic cause for tendonitis based on electron microscopic investigations of normal and diseased Achilles tendons.⁷⁷

Another result of poor perfusion under loading is the generation of toxic free radicals when perfusion is restored. Such reperfusion injury also was proposed as a causative factor for tendonitis through the destruction of tenocytes or tendon matrix by the free radicals, although this at present remains a speculative mechanism.

Proteolytic Enzymes

Various stimuli, including those mentioned previously, could result in the synthesis, release, or activation of proteolytic enzymes. Relatively little information is available on the constitutive or induced expression of proteases in tendon, although activity of procollagenase and aggrecanase was described in human and bovine tendon explants *in vitro*.^{78,79} An imbalance between the matrix synthesis and degradation of various extracellular matrix proteins is a possible mechanism whereby the tendon can be weakened and predisposed to clinical tendonitis, and *in vitro* studies have supported this as a mechanism for the weakening of tendon by cyclical mechanical load.⁸⁰ Interestingly, the influence of cyclical loading in inducing proteolytic enzyme activity appears to be exaggerated with age, possibly explaining in part the age-related increase in injury risk.⁸⁰

Factors Affecting the Loading of the Superficial Digital Flexor Tendon and Initiation of Clinical Tendonitis

Peak SDFT forces are responsible for initiating clinical tendonitis. When a tendon has been weakened sufficiently by

a preceding degenerative change, factors that increase the peak loading of the SDFT therefore also act to increase the risk of clinical tendonitis.

The SDFT is loaded preferentially at the early stage of the stride,^{8,10,81} which represents the time of highest injury risk. External factors, such as the rider's weight or hard ground, increase these peak forces, although possibly only in certain tendons. Data have suggested that landing from a jump increases the peak forces in the SDFT but not the SL.⁸² The greater height and number of fences jumped at Grand Prix-level show jumping would explain the higher incidence of injury in these horses compared with those competing at a lower level (see Chapters 69 and 115).

The influence of conformation on the risk of superficial digital flexor tendonitis is not clear. Most studies have failed to find an association between conformation and an increased risk of tendonitis.⁸³ However, one study did identify upright metacarpophalangeal joint conformation as being associated with increased risk.⁷² Foot conformation may also have an influence on the loading of the SDFT (and SL). The lowering of the toe with respect to the heel, or the raising of the heel with respect to the toe, results in reduced loading of the secondary supporter of the metacarpophalangeal joint, the DDFT, thereby increasing the loading of the primary supporter of the joint, the SL (and possibly the SDFT), often only detectable at a trot.^{11,84,85} As a corollary to this, the long-toe, low-heel conformation characteristic of TBs may actually protect horses from superficial digital flexor tendonitis. However, such alterations in tendon loading may be only short-lived.

The ground surface also potentially influences the loading of the SDFT. Soft ground may predispose to increased strains in the SDFT by allowing the toe to sink. However, using sand has been shown largely to have little effect on strains of the SDFT and DDFT.¹⁰ The effect of ground surface on the incidence of tendonitis is probably more related to determining the speed of the horse. Speed is correlated with strains of the SDFT and correlated with the incidence of SDFT tendonitis in racehorses (see Chapters 69, 106-108, and 112). Thus ground surfaces that slow the horse tend to be protective of SDFT tendonitis, whereas the driest and hardest racecourses are associated with the highest incidence of tendonitis.

Many horses develop tendonitis toward the end of a race or event when they are fatigued. Fatigue will cause greater incoordination, which can result in increased peak loads on the SDFT, thereby increasing the risk of injury.

Because tendon degeneration appears to be related to the number of loading cycles, the greater the exercise history and age, the more at risk the horse becomes. This certainly explains the strong association between age and tendonitis and may explain why older, sedentary horses still can develop tendonitis. Because the subclinical phase of tendon degeneration affects both limbs similarly, clinical superficial digital flexor tendonitis is frequently bilateral. Changes are frequently observed with ultrasonography on both limbs,⁵² although one limb is usually more severely affected than the other.

Strategies for Preventing Tendon Disease

Based on the previously described influences on tendon metabolism and function, a number of preventative strategies can be proposed. First, maximizing the quality of

Fig. 68-11 • Strategy for the prevention of tendonitis in the horse. The dotted line refers to a horse that develops strong tendons, whereas the dashed line represents a horse with poor-quality tendons at skeletal maturity (which appears to be at about 2 years of age). The latter experiences tendonitis during its racing and competitive career because of inevitable and cumulative fatigue damage to the tendon, whereas the former, although having the same degeneration, starts from a stronger point and therefore does not develop tendonitis. The early introduction of exercise during development potentially improves tendon quality (arrow), thereby subsequently reducing the incidence of tendonitis.

tendon before skeletal maturity with the early introduction of controlled exercise may be possible, thereby reducing the incidence of tendon injury in subsequent racing and competition (Figure 68-11). To test this hypothesis for tendons, two studies have investigated the ability of early exercise regimens to induce a beneficial adaptive response in equine digital flexor tendons. However, neither treadmill exercise nor exercise over ground induced any measurable effects on the digital flexor tendons,^{86,87} apart from an accelerated rate of growth in the size of the tendon.⁸⁸ This may have been because the functional ability of the tendon to withstand training and racing was not evaluated or because the additional exercise given to the exercised group of foals was insufficient. Alternatively, the natural exercise performed by foals at pasture included a large amount of jumping activity at play, which is perfectly suited to imparting high strain rates onto the digital flexor tendons, and this potentially induces maximum adaptation in both groups.

A second approach could be to identify genetic influences on the risk of tendonopathy. Certainly, the occurrence of tendonopathy in young flat racehorses may be expected to be more related to genetic factors because the injury is occurring very early in the horses's exercise history, before degeneration could have accumulated. Work is currently underway to identify any such genetic risks that could potentially be reduced by selective breeding.

Risk factors for clinical injury have yet to be fully identified, but research has indicated that certain racing surfaces (e.g., hard ground⁸⁹) and shoe types (e.g., toe grabs in Standardbreds, which increase the risk of suspensory disease⁹⁰) are associated with tendon or ligament disease, and hence avoiding them can reduce the frequency of injury substantially. Epidemiological research into identifying these risk factors systematically is hence warranted and currently underway.⁹¹

Addressing the biological basis of tendon degeneration provides a more widespread approach to preventing tendon disease in all athletic horses. The reactivation of the tenocyte synthetic machinery may be more difficult to accomplish because of the factors mentioned earlier. Therefore slowing or stopping the degenerative mechanisms is the strategy most likely to be successful.

Finally, the early detection of subtle clinical disease, or ideally in the subclinical phase of tendon degeneration, may allow an alteration of training to minimize the risk of progression to more severe disease. Although the subclinical phase is currently difficult to identify by palpation or ultrasonographic examination because it causes minimal, if any, inflammatory reaction, in the future, serological assays⁹² to detect matrix proteins released from the tendon may prove useful for detecting and monitoring this phase. Results to date are not promising.

Pathological Conditions and Phases of Tendon Healing

Once load has overcome the structural strength of the tendon, the tendon tears. The extent of this damage can vary from subtle individual fiber tears, through central defects, to generalized involvement and ultimately rupture. However, even in the last situation, the paratendon usually remains intact. After this tissue failure, repair takes place by three separate but overlapping clinical phases: the acute inflammatory phase, the subacute reparative phase, and the chronic remodeling phase.

The acute inflammatory phase begins with the onset of the clinical injury and lasts usually only 1 to 2 weeks, although this is in part determined by the severity of the injury and the antiinflammatory therapy initiated. This phase is characterized by substantial inflammation, with intratendinous hemorrhage, increased blood supply and edema, and the infiltration of leukocytes, initially neutrophils, but followed by macrophages and monocytes. The pronounced inflammation, if unchecked, results in the release of proteolytic enzymes, which, although directed at removing necrotic collagen, also digest relatively intact tendon collagen, which may cause the expansion of the lesion in the few days after the onset of the clinical tendonitis.

The subacute reparative phase begins within a few days of the injury, overlapping with the acute phase, and peaks after about 3 weeks.^{93,94} This phase is characterized by a strong angiogenic response and the accumulation of fibroblasts within the damaged tissue. These fibroblasts probably can be derived from a number of sources including the resident tenocytes, endotendon, and paratendon cells, and monocytes of vascular origin, although studies using transgenic rats have indicated that, at least in this species, the majority of the new cells that remain in the tendon after repair are derived from local tissues.⁹⁵ Increased levels of inflammation appear to be related to increased cellular infiltration and the amount of fibrosis occurring subsequently. The invading cells are responsible for synthesizing scar tissue (tendon tissue is not regenerated), characterized by small collagen fibrils, with an increased proportion of type III collagen,^{96,97} organized into haphazardly arranged fascicles. The scar tissue formed is initially weaker than tendon tissue, and hence healing tendon is predisposed to reinjury at the injury site. Such episodes of

reinjury perpetuate the first two phases and increase the amount of damaged tendon and hence the severity of the injury.

The absence of a paratendon and an externally derived blood supply within a tendon sheath may explain the relative poor response in healing in these areas. The formation of adhesions within tendon sheaths, although responsible for limiting the movement of the tendons subsequently, provides a method of allowing angiogenesis and the infiltration of cells into damaged tendon tissue within a tendon sheath. Hence, although adhesions have deleterious effects on the function of tendons, they are a normal response to encourage tendon healing in this region.

During the chronic remodeling phase, which begins several months after the injury, the scar tissue slowly remodels over a number of months. This remodeling process is associated with an increase in the proportion of type I collagen,⁹⁸ the major component of normal tendon. However, in spite of this conversion the tissue never becomes normal tendon tissue, although it is probably more functional. Controlled loading (exercise) during this phase may help promote this conversion and, even more important, may align the collagen fibrils in the direction

of force, which further improves the mechanical properties of the scar tissue. This aspect of the remodeling process is followed by assessing the fiber alignment score on ultrasonographic images (see Chapter 69).

Reinjury is unfortunately common, even after healing is complete, in the same tendon, the contralateral tendon, or other supporting structures of the metacarpophalangeal joint. As the injured tendon remodels, it becomes stronger, so that fully healed tendon (15 to 18 months after injury) is frequently stronger than normal tendon.⁹⁹ However, remodeled tendon has poor elasticity, resulting in increased strain in adjacent, relatively undamaged regions of the tendon. Therefore if reinjury occurs in the same tendon, it frequently occurs at adjacent or remote sites to the original injury. Subsequent injury to the contralateral tendon is also effectively a reinjury because of the bilateral nature of the preceding degeneration and clinical tendonitis.¹⁰⁰ Subsequent injury to the SL may be the consequence of some loss of support of the metacarpophalangeal joint, caused by substantial lengthening of the SDFT, which can occur with severe superficial digital flexor tendonitis. The SL may also suffer cumulative microdamage, which would increase further its susceptibility to injury.

Chapter 69

Superficial Digital Flexor Tendonitis

Mike W. Ross, Ronald L. Genovese, Sue J. Dyson, and Joan S. Jorgensen

The first two sections of this chapter consider the general clinical manifestations of tendonitis and then the specific surgical management of tendonitis in racehorses. The third section discusses some of the variable clinical presentations in other competition and pleasure horses and factors influencing treatment and prognosis. In this chapter we have chosen to retain the term *tendonitis* to refer to the clinical syndrome of injury of the superficial digital flexor tendon, because clinical signs of inflammation are hallmarks and tendonitis is pertinent. We recognize that others prefer the term *tendonopathy* (see Chapter 68).

■ SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN RACEHORSES

Joan S. Jorgensen, Ronald L. Genovese, and Mike W. Ross

Superficial digital flexor tendon (SDFT) injuries substantially compromise athletic performance and may culminate in a career-ending injury. The incidence of SDFT injuries in Thoroughbred (TB) racehorses ranges from 7%

to 43%,^{1,2} and such horses are most at risk because of high racing speeds or high speeds associated with jumping (steeplechase racing, see Chapter 112).³ In National Hunt horses the prevalence of tendonitis of the SDFT as detected using ultrasonographic examination was found to be 24%.⁴ In that study a reference range of cross-sectional area (CSA) measurement was obtained (77 to 139 mm²), but ultrasonographic examination could not predict injury, and variation in prevalence among yards suggested that training methods may influence injury rate.⁴ Tendonitis is quite common in the Standardbred (STB) racehorse, more so in pacers in North America than in trotters (see Chapter 108). Other performance horses, including upper-level event horses (see Chapter 117), have an increased risk of SDFT injury (see page 721). Horses used for dressage (see page 725), high-level show jumpers (see Chapter 115 and page 724), racing Arabians (see Chapter 111) and Quarter Horses (see Chapter 110), polo ponies (see Chapter 119), and fox hunters incur SDFT injuries less frequently.^{3,5,6} SDFT injury from athletic use in racehorses commonly is seen because of repetitive speed cycles over distance and possibly genetic predisposition to SDFT injury.⁷ We are aware of several TB racehorse mares and at least one TB stallion and one STB stallion that are known to have progeny with an increased susceptibility to SDFT injury compared with the normal racehorse population. Additional factors that may predispose a horse to SDFT injury include conformation (see Chapters 4 and 26), working surfaces, shoeing, training methodology, and the relationship between the level of physical fitness and the current exercise.

SDFT injury also occurs spontaneously in sedentary or lightly used horses older than 15 years of age. These tendon injuries often are severe and generally involve the proximal metacarpal region and the carpus and extend to the musculotendinous junction in the antebrachium. Many of

these injuries result in overt lameness, tendon thickening, and carpal sheath effusion (see Figure 6-18). Sometimes, however, the only clinical sign is lameness, which is often pronounced to severe, with little palpable thickening of the SDFT. Subtle swelling in the proximal aspect of the SDFT is easily missed, particularly when the limb is held in flexion. These injuries occasionally can be difficult to diagnose, requiring local analgesia and ultrasonography. Although older nonracehorses appear prone to the development of superficial digital flexor (SDF) tendonitis in the proximal metacarpal and palmar carpal regions, the condition is sometimes seen in older STB racehorses, usually pacers. In a recent study, only two of 12 nonracehorses with tendonitis of the proximal aspect of the SDFT returned to previous use with medical management; horses were significantly older (mean age of 18 years, median 17 years, and range 11 to 23 years) than a comparison group with tendonitis of the SDFT in the midmetacarpal region, and prognosis was significantly worse than in the same comparison group (10 of 22 horses with midmetacarpal SDF tendonitis returned to previous use after injury).⁸ In an unpublished study of 29 horses with tendonitis of the proximal aspect of the SDFT, mean age was 13 years (median 15, range 2 to 30 years), there were six racehorses and 23 nonracehorses of mixed use, lameness was generally pronounced, and ultrasonographic evaluation revealed injury that often involved the palmar carpal region from near the musculotendinous junction to the proximal metacarpal region.⁹ Overall, 14 of 24 horses (58%) became sound and returned to work, and five of seven horses managed surgically (desmotomy of the accessory ligament of the SDFT [ALSDFT], otherwise known as superior check desmotomy) in combination with carpal retinaculotomy and proximal metacarpal fasciotomy, or transection of the ALSDF in combination with intralesional injections of fresh bone marrow) returned to work.⁹

SDFT injuries from athletic use occur in the forelimb far more frequently than in the hindlimb. In one U.S. study of 143 TB racehorses, 58% of SDFT injuries occurred in the left forelimb and 42% in the right forelimb.¹⁰ Bilateral injury is common and has been recognized more frequently since veterinarians have been examining both limbs routinely by ultrasonography.

Most injuries in the SDFT caused by athletic use occur in the midmetacarpal region (zones 2B to 3B), but injuries also occur at the musculotendinous junction of the antebrachium, in the carpal canal and subcarpal region, and in the pastern (see Chapter 82). The plantar hock region is the most common site of SDFT injury in hindlimbs, especially in the STB racehorse (see Chapters 78 and 108). SDF tendonitis in the hindlimb in the plantar tarsal region is referred to as *curb* and is one of the collection of soft tissue injuries comprising this injury (see Figure 4-30). Occasionally this injury extends into the midmetatarsal region. Infrequently, a subtle SDFT injury is associated with tenosynovitis of the digital flexor tendon sheath (DFTS) in hunters, jumpers, and dressage horses. In the STB racehorse, tendonitis often extends to the distal metacarpal region, involving the DFTS and palmar annular ligament, and there is generalized soft tissue thickening in the palmar aspect of the fetlock region.

Racehorses with SDFT injuries traditionally have been regarded as having a guarded-to-poor prognosis for return

to racing, although the prognosis for other athletic disciplines is more optimistic. Before ultrasonography was used routinely, documentation of SDFT injury was limited. Diagnosis was based on gait evaluation and palpation of a swollen or thickened tendon. The injury was referred to as a *bowed tendon*, and morphological abnormality and severity of injury were little appreciated.

Substantial progress has been made in understanding the nature of tendon injury and the mechanisms of healing (see Chapter 68). Historically, tendon injuries have healed by the process of scar tissue formation and maturation, known as *reparative healing*. During repair, injured elastic tendon fibers are replaced with modified fibrous scar tissue, resulting in a tendon repair that is never totally normal. The quality of repair can vary greatly. Some tendon injuries repair and resolve with enough mature collagen so that they return to nearly normal size, with sufficient remodeling that approximately parallel alignment of the repair tissue results. Other injuries develop a scar, with an overall increase in tendon size, poor or random fibrous tissue alignment, and peritendinous fibrosis.

Many of the proposed therapeutic approaches are directed at maximizing the chances for a more physiologically functioning tendon. Therapy requires a multifaceted approach that reduces the acute inflammatory response and hemorrhage in the acute phase and improves fiber alignment during the long rehabilitation phase. The ultimate goal of any treatment and management program is to maximize the chances for a tendon to repair with adequate strength and elasticity for a return to a similar level of performance with the lowest risk of reinjury. Recently attempts have been made to heal equine soft tissue injuries using principles of *regenerative healing*. Regenerative healing occurs in fetal tissues and involves restoration of tissue without scar formation. Regenerative techniques involve the use of freshly harvested or cultured mesenchymal stem cells (MSCs) derived from bone marrow, adipose tissue, or other sources in an attempt to heal adult tissues in a manner similar to healing seen in a fetus (see Chapter 73). Improvement was reported in nine of 12 horses with SDF tendonitis injected with undifferentiated autologous MSCs, and the technique was found to be safe and efficacious.¹¹ Reimplantation of autologous bone marrow-derived MSCs in 168 TB racehorses (National Hunt horses) with SDF tendonitis resulted in a substantially smaller reinjury rate (18%)¹² than that previously reported (56%)¹³.

It is important to recognize the variables that may affect the ultimate prognosis when SDFT injuries are managed. Not all tendon injuries are the same, and case management depends on the specific injury, medical factors, and other nonmedical factors.

CLINICAL SIGNS

Clinical signs of SDFT injury in racehorses vary considerably depending on the location of the primary injury, type of injury, severity, and timing of the examination. Occasionally, clinical signs may be delayed by days or weeks. Furthermore, a lack of correlation may exist between the severity of the injury and the severity of tendonitis in any given individual, especially in the more common core tendon injuries experienced by TB racehorses. In contrast, STB racehorses more often experience lateral and medial

border tendon injuries that result in substantial swelling but less severely injured tendon fascicles. Identification of subtle, yet important, reinjury by clinical evaluation may be difficult because of previous tendon thickening. Thus ultrasonographic imaging is essential to confirm clinical signs and to evaluate the extent of injury to the SDFT.

Lameness

Pain on direct compression of the SDFT and mild swelling are the earliest signs of SDF tendonitis. Lameness is often not present at first, a characteristic that often delays veterinary intervention. Because horses are not often overtly lame in the early stages of tendonitis, and subtle pain and swelling either are missed or respond to symptomatic therapy, lesions can progress in severity. The degree of lameness associated with a tendon lesion in the midmetacarpal region is usually correlated with the severity of the injury. Slight to high-slight (category II to IV) injuries generally are not associated with any appreciable lameness, whereas mid-moderate to high-moderate (category V) injuries cause only transient lameness. Most severely injured tendons (category VI), or a total rupture of the SDFT, result in at least transient lameness, which may be severe. In contrast, lesions in the carpal canal or proximal metacarpal region (zones 0 and 1A) consistently are associated with pronounced lameness.

Swelling

For assessing tendon injuries, swelling is defined as subcutaneous or peritendonous fluid accumulation. Digital palpation reveals a soft or semifirm, diffuse or focal fluid accumulation that may prohibit exact palpation of the SDFT. Subcutaneous swelling can be associated with tendon injury, especially in the acute stage of injury. Careful digital palpation of the limb held in a semiflexed position may reveal slight crepitus in an acutely injured tendon. However, subcutaneous inflammation or hemorrhage is not associated invariably with tendon injury. Examples of focal edema or hemorrhage without substantial SDFT injury include swelling associated with cording of the midmetacarpal region secondary to a malpositioned bandage or subcutaneous swelling in the proximal or distal metacarpal region caused by malpositioned tendon boots or stable (stall) bandages. An example of diffuse swelling is pitting edema (see Chapter 14), occasionally caused by external blistering. Diffuse filling also may reflect a subsolar abscess or cellulitis.

Thickening

Thickening or enlargement specifically indicates SDFT swelling secondary to injury or a thickened end-stage repair from a previous injury. In this context, subcutaneous swelling is not appreciable, but a palpable enlargement of the SDFT occurs. In many slightly and diffusely injured tendons, thickening may be difficult to appreciate, and careful comparison with the normal contralateral limb may be required to identify SDFT enlargement. In more severely injured tendons examined in the subacute phase, enlargement generally can be felt. Two clinical situations in which assessing SDFT thickening is difficult are a focal SDFT injury in the subcarpal region, where the tendon is enveloped by the retinaculum, especially in colder climates when limb hair is long, and instances of SDFT injury within

the DFTs that also is associated with tenosynovitis. Tenosynovitis makes distinguishing between tendon thickening and tendon sheath fibrosis difficult.

When palpating the SDFT, one should always determine if the medial and lateral borders of the SDFT can be separated clearly from the accessory ligament of the deep digital flexor tendon (DDFT) and the tendon itself. If both digital flexor tendons are slightly enlarged, detection of abnormality is more difficult; however, frequently the margins of both tendons are more rounded than normal. Assessing the flexibility of the SDFT also is useful, because abnormal stiffness usually reflects previous injury.

Heat

Increase in surface temperature often can be the earliest and most subtle clinical sign of SDFT injury or reinjury. Digital appreciation of an increase in skin temperature, or thermography, often can indicate tendon inflammation. Because extensive use of liniments and daily bandaging in racehorses also increases skin temperature, one must be careful when making this assessment.

Sensitivity to Direct Digital Palpation

A painful response to direct digital palpation is often a reliable clinical test for tendon injury and may be the earliest clinical sign detectable (see Figure 6-15). Examination is best performed by holding the limb in a semiflexed position and palpating with the thumb and forefinger systematically from proximal to distal in the metacarpal region in an effort to elicit a painful response. When a sensitive area is palpated, the horse generally flinches. The examination has many caveats. If a sensitive response is elicited bilaterally, the horse may merely be hyperresponding to increased pressure and possibly has no injury. Not all horses with tendon injury have a painful response. Horses with blistering of the skin, adverse local drug reaction, infection, or cording are also hyperresponsive and more reactive than those with a tendon injury. In addition, extreme sensitivity to direct palpation coupled with focal or diffuse swelling may indicate a problem not related to the tendon.

Tendon Profile

Evaluation of the tendon profile with the limb in a full weight-bearing position can provide valuable information. In a normal limb the metacarpal region has a straight palmar profile. A normal SDFT should be superficial and parallel to the DDFT. It is important to examine the profile from all possible angles. With a slight injury, the tendon often has a normal profile when viewed from the lateral aspect and a convex or bowed profile from the medial aspect, or vice versa. In fact, slight changes on tendon profile are often most obvious when examining the horse visually from the opposite side (Figure 69-1). It takes considerable damage to the SDFT to change the visually detected profile of the tendon, and ultrasonographic evidence of tendon injury is often much more pronounced than expected. In a horse with an acute total rupture, little swelling and thickening may be present if the leg is examined within 2 hours of the injury. However, with the limb in full weight-bearing position, one may note hyperextension of the metacarpophalangeal joint. In this case, digital palpation along the palmar aspect of the tendon reveals a

Fig. 69-1 • **A**, Photograph of the right front (RF) metacarpal region taken from the left side showing swelling of the superficial digital flexor tendon (SDFT) in the midmetacarpal region (*arrow*). Often the change in profile of the SDFT is best seen from this perspective (the left forelimb can be seen in the foreground). **B**, Transverse (left) and longitudinal ultrasonographic images of the RF SDFT in this 3-year-old Thoroughbred gelding racehorse with substantial injury of the SDFT. A central core lesion (double-headed arrow) and enlargement of the entire SDFT can be seen. Ultrasonographic evidence of tendonitis is often much more extensive than is realized during visual inspection of the limb, a fact that may delay veterinary intervention. This horse underwent successful surgical management using desmotomy of the accessory ligament of the SDFT (superior check desmotomy) and desmoplasty (tendon splitting).

1- to 2-cm defect in the SDFT. Digital palpation with the limb in a semiflexed position also reveals laxity and excessive mobility of the tendon.

Swelling in the Distal Metacarpal Region

In horses with chronic tendonitis of the SDFT or in those with only tendonitis of the SDFT in the distal metacarpal region, there can be involvement of the DFTS and the palmar annular ligament (PAL). Chronic, distal metacarpal tendonitis of the SDFT in the region of the PAL is common in STB racehorses, polo ponies, and older TB racehorses (Figure 69-2). It is important to differentiate clinical syndromes in this region. In horses with chronic tendonitis of the SDFT, the primary lesion is the tendon injury with subsequent restriction of movement through the “fetlock canal” (reduced gliding function) by the PAL. Thus the PAL is not primarily involved but is merely a “passenger” in the clinical syndrome. In these horses palmar annular desmotomy is critical to restore gliding function and to decompress the swollen SDFT, but there is no actual palmar annular desmitis. Primary palmar annular desmitis, tenosynovitis of the DFTS, and deep digital flexor (DDF) tendonitis are other clinical syndromes that cause swelling in the distal, palmar metacarpal region and should be differentiated from distal SDFT lesions and compression by the PAL (see later discussion and Chapters 70 and 74).

Tenosynovitis of the Carpal Sheath or Digital Flexor Tendon Sheath

Tenosynovitis may be associated with a tendon injury or may be a clinical entity without tendon injury (see

Fig. 69-2 • Photograph of the left metacarpal region of an aged Standardbred gelding racehorse with chronic, severe tendonitis of the left front superficial digital flexor tendon (SDFT). Notice that the thickened SDFT is compressed by the palmar annular ligament (PAL) (*arrows*) in the palmar fetlock region. The PAL is a secondary problem causing restriction of gliding function of the injured SDFT. Palmar annular desmotomy in combination with desmotomy of the accessory ligament of the SDFT was performed successfully. Previous cryotherapy for suspensory desmitis was performed (white hairs).

Chapters 74 and 75). Ultrasonographic evaluation is required to appreciate tendon injury in the presence of tenosynovitis.

Tendon Injury Limited to the Pastern

Injury to one or both of the SDFT branches of the pastern is generally but not always associated with branch thickening and a painful response to direct digital pressure (see also Chapter 82). This is best appreciated with the limb held in a semiflexed position and direct pressure placed on the branch with the clinician's thumb. Injury to the SDFT branch(es) may be associated with tenosynovitis. Injury to the branches of the SDFT should be carefully differentiated from injuries of the distal sesamoidean ligaments.

MANAGEMENT OF THE ACUTE PHASE OF TENDON INJURY IN RACEHORSES

In most horses with subtotal SDFT injuries in the acute phase, antiinflammatory and supportive management is instituted. A variety of treatment regimens are available. For the most part, systemic nonsteroidal antiinflammatory drugs (NSAIDs) such as phenylbutazone (4.4 mg/kg/day) for 7 to 10 days and a single dose of systemic corticosteroids such as dexamethasone (0.04 mg/kg) are included in the initial therapy. Perilesionally administered corticosteroids are considered contraindicated in horses with tendon injuries, especially long-term use, because these drugs are thought to delay collagen formation. However, some clinicians use a single perilesional dose of triamcinolone acetonide (6 to 9 mg) or methylprednisolone acetate (40 mg) (dystrophic mineralization occasionally has been associated with methylprednisolone therapy) in horses with slight, peripheral tendon injuries in STB racehorses, especially when associated with curb (see Chapter 78). Practitioners often administer a course of polysulfated glycosaminoglycans (PSGAGs; 1 vial per week for 4 weeks) in the acute stage.

Physical therapy is indicated, and we recommend icing for 1 to 2 hours once or twice a day, with application of a poultice, or simple support bandaging for horses with subtotal injuries. Casting may be indicated for horses with rupture of the SDFT. Exercise generally is restricted to stall (box) rest or limited hand walking. In horses with subtotal injuries, we prefer to keep the injured limb shod in a fully grooved bar shoe, with a straight hoof-pastern axis, so that the metacarpophalangeal joint position is normal in a standing position. We do not advocate raising or lowering the heel to an exaggerated position. We perform an ultrasonographic examination within the first few days and then again 3 to 4 weeks later. Sometimes tendon splitting is advised for horses with small core lesions.

INJURY ASSESSMENT AND GOALS FOR AN ATHLETIC OUTCOME

Qualitative assessment combines the physical findings and a subjective ultrasonographic appraisal. This gives an accurate diagnosis, but we also strongly encourage the use of quantitative ultrasonographic evaluation. This includes data such as CSA and echogenicity and fiber alignment scores (see Chapter 16).

Optimal healing of SDFT injuries depends on managing a number of variables, including the personality of the

horse; its age, sex, athletic use, conformation, injury episode number, and maximal level of exercise attained; and the severity of the injury. For instance, a 4-year-old TB gelding racehorse that has an upright conformation, has never raced, and experiences a severe (category VI) SDFT injury after one gallop has a poor prognosis with any treatment. If this horse were to sustain a small core lesion of the SDFT, its prognosis would be more guarded because of its conformation and the exercise level at which injury occurred compared with a similar injury in a well-conformed, seasoned racehorse.

Athletic outcome of a racehorse may be divided into three categories: successful, meaning completion of five or more races (I); partially successful, completion of one to four races (II); and failure, meaning reinjury occurred before the first race was completed (III). Horses with successful outcomes can be further subdivided into those with reinjury and those with no reinjury. Horses with partially successful outcomes can be further subdivided into those sustaining reinjury and those injuring the contralateral SDFT or a forelimb suspensory ligament.

ULTRASONOGRAPHIC EVALUATION AND CATEGORIZATION OF INJURIES

If clinical evaluation indicates a possible SDFT injury, ultrasonography should be used to confirm the diagnosis and objectively assess the severity of injury. Sequential examinations provide a guide to controlled exercise management and are used to assess progress of repair and attempt to establish an optimal time to return to full work.

The acquisition and assessment of accurate ultrasonographic data require high-quality images, and it is important to develop a rigid, standardized technique (see Chapter 16). The ultrasonographer must take primary responsibility for image interpretation. For a second person to give an opinion on images previously obtained by someone else is often difficult.

Quantitative ultrasonographic data include CSA, percentage of CSA occupied by a lesion, grade of echogenicity of a lesion (type or echo score [TS]), and assessment of fiber bundle alignment in longitudinal images (fiber alignment score [FAS]). Each of these data points is assessed at every defined level of the limb (zone), and they are then summed to provide total scores. These scores then can be used to categorize an injury as minimal (category III), slight (category IV), moderate (category V), or severe (category VI) (see Chapter 16). The following comments apply to forelimb and hindlimb injuries, although reference is made to only the metacarpal region.

Initial Evaluation

Early examination of a suspected new injury of the SDFT may not reveal any anechoic or hypoechoic lesions. However, if the CSA of a single zone is more than 39% larger than in the contralateral limb, or if the total of six of seven zones is more than 14% larger than in the contralateral limb, then tendonitis should be suspected (category II). If tendonitis cannot be substantiated by ultrasonography, despite soft tissue swelling, then conservative management is indicated. The horse should be restricted to walking exercise for at least 72 hours and then reevaluated clinically

and ultrasonographically. Symptomatic therapy includes systemic NSAIDs, daily icing, and mild leg liniments or sweats with limb bandaging. One must recognize that sometimes a lesion(s) cannot be identified ultrasonographically for at least several days or longer.

Within 7 days of injury a hypoechoic or anechoic lesion may represent tendon fascicle damage, hemorrhage, or inflammatory exudates and is most likely a combination of all three. Distinguishing the relative contributions of each or determining accurately the severity of injury, which may be underestimated or overestimated, is not possible. Initially, damaged collagen fibers may be grossly intact but nonfunctional, resulting in reflecting echoes. Ongoing enzymatic degradation and further injury caused by pressure necrosis may result in a lesion deteriorating over 3 to 4 weeks. In contrast, infrequently the hemorrhage and inflammatory exudates resolve over the following 3 to 4 weeks and result in a great improvement of the lesion, and the injury to fiber bundles may not be as serious as initially indicated.

Baseline Evaluation

If an initial examination is done within 1 to 7 days of a new injury or a reinjury, we strongly advise that a second ultrasonographic evaluation be performed 2 to 4 weeks (preferably 4 weeks) later to obtain baseline data about the severity of injury (see Chapter 16).

SUBACUTE PHASE TREATMENT AND LONG-TERM REHABILITATION

History of Treatment in Racehorses

A wide variety of short-term and long-term treatment programs for SDF tendonitis are used, sometimes implemented regardless of the severity of the injury or reinjury, and with or without prolonged rest or controlled exercise. No comprehensive reports comparing various treatments of similarly injured tendons are available, and therefore proposing specific recommendations that will give the best prognosis for return to racing is difficult.

A comprehensive retrospective study of TB and STB racehorses currently is being performed to compare the rate of return to racing among a variety of therapeutic regimens for minimal (category III), slight (category IV), moderate (category V), and severe (category VI) tendon injuries documented by ultrasonography. Therapies include pasture turnout, external blistering, internal blistering, intralesional therapies (excluding β -aminopropionitrile fumarate [Bapten]), or a combination of these. In addition, the amount of layup time is being considered for each category of injury. If all therapeutic regimens are combined (Figure 69-3), preliminary data indicate that few racehorses successfully return to racing without reinjury (athletic outcome I, completed five or more races), especially with severe injuries.¹⁴ In addition, these data demonstrate that few racehorses are able to return to racing and not experience reinjury of the SDFT, sustain injury to the contralateral SDFT, or injure the suspensory apparatus (subcategories IB and IC). Ultimately, we hope that this research helps to determine optimum therapy for specific lesions and better equip the veterinarian to provide accurate prognostic information.

Fig. 69-3 • A successful return to racing becomes increasingly difficult as the severity of tendon injury increases. Treatments for slight (category IV), moderate (category V), and severe (category VI) superficial digital flexor tendon injuries including pasture turnout, external or internal blistering, intralesional injections (excluding β -aminopropionitrile fumarate), or a combination of these were assessed for their success in return to racing. Athletic outcome categories (AOCs) were separated into five groups. AOC IA refers to those horses that have successfully raced at least five times with no reinjury. AOC IB + C includes those that have raced at least five times but have reinjured the same tendon (group B) or the contralateral tendon (group C). AOC II includes those that have raced successfully one to four times and includes tendons that have been reinjured, whereas horses with tendon injuries in AOC III have never raced successfully. An additional group of all those that completed at least one race was included. Data are represented as the percentage of tendons in each injury category that resulted in the ultimate AOC.

Symptomatic Treatment with Continued Exercise

If the decision is made to treat a horse with an injured tendon symptomatically and continue exercise (racing), serial ultrasonographic examinations should be performed, because changes in size or echogenicity may be detected before clinical signs are obvious. If the ultrasonographic examination demonstrates progressive injury or instability and the horse is not athletically (economically) productive, stopping racing and considering long-term rehabilitation would be wise. Naturally, any racehorse racing with an injured tendon is risking more serious injury.

A retrospective study of 209 tendons from 207 TB racehorses was performed to determine if quantitative ultrasonographic assessment could aid in accurately defining an SDFT injury and provide evidence for determining a prognosis for racing in horses that underwent symptomatic treatment with continued exercise. Eighty-eight percent of horses that had no or minimal injury (categories I and III) started more than three races, whereas 12% failed. Thirty-five percent of horses with slight (IV), moderate (V), or severe (VI) injuries started more than three races, but 82% had recurrent injury.¹⁰ Ultrasonography is therefore helpful to determine the prognosis for returning to racing. Symptomatic therapy while continuing to race is a viable therapeutic option for minimal tendon injuries.

Consider a 3-year-old TB gelding racehorse with a swollen left front SDFT after a race (Figure 69-4). Quantitative ultrasonographic analysis revealed a total lesion area of 13%, TS of 7, and total FAS of 7, indicating a mildly injured (category IV) tendon. The horse was treated symptomatically with antiinflammatory medication and continued to race. After 4½ months and six races the horse was racing well, having earned more than \$34,000. After two additional races, the total lesional area increased and the

Zone	Structure Size (mm ²)	Lesion Size (mm ²)	Fiber Alignment Score	Type/Echo Score	Clinical Findings
1A	87	—	—	—	Lameness: 0/5
1B	82	11 (14.25%)	—	1	Swelling: 2/5
2A	88	5 (6.18%)	—	1	Thickening: 1/5
2B	108	16 (14.84%)	1	1	Sensitivity: 2/5
3A	139	14 (10.47%)	3	2	Heat: 2/5
3B	123	36 (29.19%)	3	2	Tendon sheath involvement: 1/5
					Fetlock sinking: 0/5
Totals	627	82 (13%)	7	7	Fetlock flexion: Negligible

Bold type indicates maximal injury zone.

Fig. 69-4 • Data derived from an initial computerized scan of a 3-year-old Thoroughbred racehorse actively racing with a category IV injury (<15% tendon lesion). The type (or echo) score and fiber alignment score are similar, indicating a new lesion. Zone 3B was determined to be the maximal injury zone, with a 29% increase in size compared with the contralateral limb.

Zone	Structure Size (mm ²)	Lesion Size (mm ²)	Fiber Alignment Score	Type/Echo Score	Clinical Findings
1A	109	—	—	—	Lameness: 0/5
1B	95	—	—	—	Swelling: 1/5 (zone 3C)
2A	122	—	—	—	Thickening: 2/5
2B	157	11 (7.38%)	1	2	Sensitivity: 0/5
3A	136	14 (9.59%)	1	1	Heat: 1/5
3B	178	28 (15.68%)*	2	1	Tendon sheath involvement: 0/5
3C	164	23 (13.90%)*	3	3	Fetlock sinking: 0/5
Totals	961	76 (8%)	7	7	Fetlock flexion: Negative or no abnormality detected

Bold type indicates maximal injury zone.

*Evidence of focal instability of echogenicity near the metacarpophalangeal joint.

Fig. 69-5 • Data derived from a computerized scan of a right forelimb superficial digital flexor tendon injury 11½ months after the baseline scan and 6 weeks after galloping was resumed. Before galloping, the total cross-sectional area was 975 mm², which decreased to 961 mm². However, new hypoechogenic lesions were documented in zones 3B and 3C, indicating an unstable healing process.

horse's performance decreased. Long-term therapy with time off was instituted. STB racehorses are generally more successful than TBs in continued performance with a tendon injury.¹⁴

A retrospective study of pretraining (exercise level 5) ultrasonographic data from 106 injured racehorses provided four criteria that we use as a guideline for an optimum return to racing¹⁵:

1. At least a 60% decrease in category IV total lesional area, or fewer than 12% total hypoechogenic fiber bundles for all categories of severity of injury
2. At least a 10% to 15% decrease in total CSA from baseline for all categories of injury (a relatively greater decrease in more seriously injured tendons)
3. At least a 70% decrease in the total TS (ideally <4; the closer to zero, the better)

4. At least a 75% decrease in the total FAS (ideally <4; the closer to zero, the better) before advancement to exercise level 5

The horse should meet at least three of the four criteria, with only minimal failure of the other criterion. Horses that met all criteria or failed only one had a 50% chance to be successful as defined by completing five races. If a horse failed more than one criterion, the chance of reinjury before racing one race was 85%. All horses (100%) that failed all criteria had reinjury.

Ultrasonographic evaluation is used to monitor tendon stability during training. For example, ultrasonographic examination of a right front SDFT 11½ months after the baseline scan and after 6 weeks of galloping indicated stable total CSA values but increased hypoechogenic tendon fascicles in zones 3B and 3C (Figure 69-5). Clinically, increased

Zone	Structure Size (mm ²)	Lesion Size (mm ²)	Fiber Alignment Score	Type/Echo Score	Clinical Findings
1A	88	—	—	—	Lameness: 0/5
1B	116	—	—	—	Swelling: 0/5
2A	114	9 (7.71%)	1	1	Thickening: 2/5
2B	151	17 (11.27%)	1	1	Sensitivity: 0/5
3A	160	16 (10.40%)	1	1	Heat: 0/5
3B	202	53 (26.37%)*	3	3	Tendon sheath involvement: 0/5
3C	191	27 (14.06%)*	3	3	Fetlock sinking: 0/5
Totals	1022	122 (12%)	9	9	Fetlock flexion: Negative or no abnormality detected

Bold type indicates maximal injury zone.

*Evidence of focal instability of echogenicity near the metacarpophalangeal joint.

Fig. 69-6 • Data derived from a computerized scan of the same limb as in Figure 69-5. After 16 days of continued exercise, clinically significant reinjury is documented by an increase in total cross-sectional area to 1022 mm², worsening type score and fiber alignment score in zones 3B and 3C, and an increase in the total percentage hypoechoic volume of the injury. These findings illustrate the importance of quantitative analysis in monitoring tendon healing and predicting responses to an aggressive treatment program.

heat and swelling in the distal metacarpal region were found, which indicated tendon instability at the current exercise level and a high risk of reinjury with continued training. The trainer was unwilling for economic reasons to pursue another long-term treatment program and decided on an intermediate program of 30 days of ponying (leading the horse from another horse) and swimming. Six weeks later substantial reinjury of the SDFT occurred in the distal metacarpal region (Figure 69-6). Use of serial ultrasonographic monitoring is discussed in detail elsewhere (see Chapter 16).

Common Long-Term Treatment Programs

Controlled Exercise and Time Out of Training

A graded exercise program based on severity of the injury and the ultrasonographic progress during rehabilitation has been used.¹⁶ Turnout in a large paddock was not permitted. The time out of training ranged from 9 to 12 months, depending on the initial severity of the injury and ultrasonographic progress. Twenty-eight TB racehorses were managed in this manner, and 20 (71%) of the 28 returned to racing. Only two (25%) of eight horses treated with time off and large pasture exercise had a successful outcome. The difference between horses managed in an uncontrolled fashion, using unlimited exercise while being turned out, and horses managed in a vigorously controlled exercise program is hugely important.¹⁶ One of us (MWR) feels strongly that “turnout is the antithesis of healing,” and the results of the study by Gillis emphasize the point. Currently no consensus exists on the treatment of choice for SDF tendonitis in racehorses, but most treatment regimens are combined with a controlled exercise program and serial ultrasonographic assessment. One of us (MWR) feels strongly that surgical management is important. Most horses with category II (tendonitis without lesions perceptible by ultrasonography) or III (total echogenicity score less than 3) lesions have a reasonably favorable prognosis

for successful return to racing (defined as five or more races [athletic outcome I]) if they are confined to controlled exercise for sufficient time.

External and Internal Blistering, Pin Firing, and Time Off for Long-Term Rehabilitation

One of the most common therapeutic regimens in the United States for rehabilitating racehorses with SDFT injuries includes some sort of counterirritation (see Chapter 88), plus controlled exercise or turnout into a large pasture. Many counterirritation options exist, including external blistering agents such as a variety of iodine-based liniments, internal peritendinous injection of 2% iodine in almond oil (internal blister), and pin firing. Several reasons exist for the persistent use of these treatment regimens, in spite of evidence suggesting that turnout exercise is contraindicated and the limited research suggesting that external blistering and especially pin firing have no beneficial effect on tendon injury repair.¹⁷ No alternative therapeutic regimens result in a consistent return to racing without reinjury or injury to another soft tissue structure. Tradition is strong, and most newer surgical and medical treatment regimens are expensive, even though the prognosis remains guarded.

Counterirritation promotes angiogenesis, and, when used, exercise is restricted. In a retrospective study of 54 TB and STB racehorses treated with pin firing or external blistering and given more than 6 months out of training, 23 (43%) returned to race at least once.¹⁸ Ten (19%) of these horses returned to racing without experiencing reinjury to the tendon. These data indicate that racehorses treated by counterirritation can return successfully to racing, and so counterirritation will continue to be used until alternative methods prove to have significant and consistent improved athletic outcomes. If counterirritation is the treatment option selected by the trainer or owner, athletic outcomes may be improved if treatment is combined with a controlled exercise program and serial

ultrasonographic examinations. We recommend reexamination every 2 months to evaluate the quality of repair and to determine if the current exercise program is excessive for any given stage of healing.

Intralesional β -Aminopropionitrile Fumarate and Controlled Exercise

The following information regarding β -aminopropionitrile fumarate is included as it appeared in the first edition of this textbook, because it is historically important and lessons learned from the long-term study of the effects of the chemical are important. During study of the effects of the chemical, work by Genovese, Reef, and others demonstrated the value of serial ultrasonographic examinations and fiber score assessment in horses being managed in the various treatment protocols. They and others, including Dyson (see discussion of SDF tendonitis in nonracehorses, later) believed strongly in the value of the chemical in combination with strict rehabilitation. Currently there is no commercially available source to acquire the chemical, and use of it has largely ceased in North America (MWR).

β -Aminopropionitrile fumarate is a toxic substance found in the seeds of the plant *Lathyrus odoratus* (sweet pea). If β -aminopropionitrile fumarate is injected into an injured tendon 30 to 90 days after injury, it binds to the enzyme lysyl oxidase and inhibits the deamination of lysine. This temporarily blocks cross-linking between collagen fibers and improves the quality of repair, if combined with controlled exercise, to generate piezoelectric forces and encourage axial alignment of the repairing collagen fibers. In a naturally healing tendon the collagen fibers may be aligned randomly, whereas treatment with β -aminopropionitrile fumarate may encourage parallel alignment of the fibers, resulting in a stronger, more physiological repair. Treatment with β -aminopropionitrile fumarate combined with a controlled exercise program has resulted in superior healing, with more type I collagen fibers and improved longitudinal fiber alignment than in horses treated without exercise.¹⁹ β -Aminopropionitrile fumarate does not increase tenocyte formation and only affects the orientation of the scar and does not hasten repair. Theoretically intralesionally administered β -aminopropionitrile fumarate is indicated for horses with moderate to severe injuries, when a large volume of the tendon will be repaired by scarring.

β -Aminopropionitrile fumarate is administered 30 to 90 days after injury and is used at a rate of 1 mL (0.7 mg) per 3% total lesional area, up to a maximum of 10 mL (7 mg). Pretreatment quantitative ultrasonographic evaluation is important for establishing the anatomical extent of the lesion to be treated and the dose required.

Several clinical trials with β -aminopropionitrile fumarate have been performed. Genovese reported an improvement in quantitative ultrasonographic morphology.²⁰ In a study in the United Kingdom, six of seven TB flat racehorses failed to complete one race,³ but a trial in the United States determined that 50% of treated horses returned to racing and completed at least five races.²¹ Clinical trials performed in Ohio compared the results of β -aminopropionitrile fumarate treatment (75 horses) with use of a placebo (10 horses). All horses followed a similar exercise program. In phase 1, horses were out of training for less than 6 months, but the rate of reinjury was high. In phase 2, convalescence

Fig. 69-7 • Superficial digital flexor tendon injuries treated with β -aminopropionitrile fumarate were compared with placebo groups in two phases of the study. Phase 1 required less than 6 months of layup time, whereas phase 2 studies increased the convalescent time to at least 6 months for category IV injuries, 8 months for category V, and 10 months for category VI injuries. The percent of the total number of tendons was divided into three groups: success (raced at least five times after injury), partial success (raced one to four times), and failure (never raced). In phase 1, injuries including mild (category IV), moderate (category V), and severe (category VI) were grouped together to determine outcome; in phase 2 only moderate and severe categories were grouped.

was increased, based on the ultrasonographic grading of the severity of the injury. Horses with a category IV lesion had at least 6 months out of training; this was extended to 8 months for horses with category V lesions and 10 months for those with category VI injuries. In phase 2 the success rate increased (Figure 69-7).

Thirty-seven percent of treated horses with moderate (category V) or severe (category VI) injuries returned to racing without recurrence of injury; 57% failed to race once. None of the placebo group returned to racing without recurrent injury, and 71% failed to race once. Although slight (category IV) and moderate (category V) tendon lesions may appear healed clinically and by ultrasonography (with qualitative and quantitative assessment) 4 to 5 months after treatment, the strength of repair is inadequate to permit return to full training, and further time is essential for collagen maturation and remodeling.

Improvements in management have resulted in increased success with the use of β -aminopropionitrile fumarate. Racehorses with career-ending category VI injuries also have been rehabilitated for low-level dressage or eventing, or as show hunters or show jumpers.

Intralesional or Perilesional Administration of Hyaluronan

Hyaluronan is a component of the tendon matrix, directly influences collagen fibril formation and aggregation, and stimulates fibrillogenesis of type 1 collagen. Hyaluronan may decrease adhesion formation during tendon repair. In a clinical field trial, treatment of horses with acute anechoic tendon lesions with a single intralesional injection of high-molecular-weight hyaluronan (Hylartin-V) was compared

with use of a saline placebo. Ultrasonography showed that 60% of lesions resolved in the hyaluronan group compared with 24% resolved in the placebo-treated group, but athletic outcome results were not reported.²² A separate long-term study comparing reinjury rate at a minimum follow-up of 2 years after treatment with intralesional high-molecular-weight hyaluronan combined with a controlled exercise program or controlled exercise alone found no significant difference in recurrence of injury. Neither study reported any adverse reaction to intralesionally administered high-molecular-weight hyaluronan.^{22,23}

Corticosteroids

Repeated treatments with corticosteroids may impair tendon healing, but many veterinarians have anecdotally reported that low doses of corticosteroids combined with hyaluronan can be used successfully to manage category III or IV peripheral SDFT lesions in STB racehorses. This practice seldom is used in TB racehorses because of the concern of acute breakdown, an uncommon occurrence in the STB racehorse. A single perilesional injection of 6 to 9 mg triamcinolone acetate with 10 to 20 mg hyaluronan is suggested. Methylprednisolone acetate is not recommended, because it may be associated with development of dystrophic mineralization. It is important to note that continued exercise during this treatment may lead to more serious injury. Therefore close clinical and ultrasonographic monitoring, modification of training schedules (downscaled), and spaced, selected races for optimal results are recommended.

Intralesional and Systemic Administration of Polysulfated Glycosaminoglycans

PSGAGs are reported to inhibit macrophage activation and collagenase and metalloproteinase activity and therefore may be useful in the acute stage of tendon injury or reinjury.² The suggestion has been made that PSGAG may stimulate tenocyte repair. However, in a long-term clinical study, no significant difference was found in the recurrent injury rate of horses with tendons treated with systemic or intralesionally administered PSGAGs compared with controlled exercise alone.^{23,24} However, because tendon injuries are potentially career threatening, one author (RLG) often recommends weekly systemic administration of PSGAGs for 4 to 6 weeks for horses with acute injuries of less than 8 weeks' duration. This is combined with other long-term rehabilitation procedures.

Physical Therapies

Physical therapeutic approaches for long-term rehabilitation of a tendon injury, such as therapeutic ultrasound, low-frequency laser, extracorporeal shock wave therapy, cryotherapy, and electromagnetic field therapy frequently are used by owners, but no clinical studies document their therapeutic value over conservative, controlled exercise management.

Other Proposed Long-Term Treatments

See Chapter 73 for a complete discussion of alternative treatments including MSCs, growth factors, and other methods to stimulate regenerative or reparative healing. See the following discussion regarding the surgical management of SDF tendonitis.

■ SURGICAL MANAGEMENT OF SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Mike W. Ross

Surgical management remains a most useful and viable alternative to all other methods currently employed to augment reparative and regenerative healing of an injured SDFT. Time-honored principles such as decompression, improved gliding function, reduced load, and protection of inelastic scar formation are achieved with surgical management. Postoperative exercise and rehabilitation must be vigorously controlled and are optimized if a philosophy of restricted, controlled exercise without uncontrolled, unlimited turnout exercise is adopted.

TRANSECTION OF THE ACCESSORY LIGAMENT OF THE SUPERFICIAL DIGITAL FLEXOR TENDON

Since Bramlage first described transection of the ALSDF, also known as *superior* or *proximal check desmotomy*, as a novel surgical treatment for tendonitis of the SDFT, there has been controversy regarding efficacy of the procedure.¹⁻⁶ Early, optimistic results were reported in TB racehorses and included 32 of 36 horses (89%) that returned to racing and 25 horses that competed at a level equal to or above the preinjury level.³ The results of that study were criticized because criteria for success, defined as completing two races and starting a third, were lenient, and horses developing contralateral limb lameness, including tendonitis, were excluded. Results from a larger group of TB racehorses, using a more strict definition of success, revealed that 97 of 137 horses raced (71%) and 70 horses (51%) made more than five starts after surgery, but average earnings decreased in 58% of horses. In that study the mean time from surgery to first start was 353 days.⁴ The proposal was that the ALSDF heals after transection but in an elongated fashion, causing an increased length of the bone-ligament-tendon-bone (radius-ALSDF-SDFT-proximal and middle phalanges) construct.⁵ In a smaller, separate study evaluating the long-term effects of transection of the ALSDF and other treatments, 53% of flat racehorses, 58% of steeplechasers, and 73% of hurdlers competed in five or more races after surgery.⁶ Clearly, with more strict definitions of success, earlier results have been downgraded but do appear superior to results from unmonitored conservative therapy alone. For instance, one estimate claims that only 20% of TB racehorses will complete three or more races after injury.⁷ In a separate study of TB horses treated without surgery, 52% returned to racing, but 48% had recurrent tendonitis.⁸ More recently, 20 of 28 (71%) TB racehorses were managed successfully nonsurgically with careful rehabilitation (controlled exercise, no turnout), serial ultrasonographic examinations, and a minimum of 8 to 9 months of rest.⁹ Clearly, controlled exercise and careful clinical and ultrasonographic examinations are important components of any rehabilitation program. In contrast to other reported results, another study found no difference in prognosis in TB racehorses treated with transection of the ALSDF compared with conservative management and in fact found horses that underwent surgery to be at risk to develop suspensory desmitis.¹⁰

In the STB racehorse, results after transection of the ALSDF are clearly superior to those achieved in the TB racehorse and published results in horses receiving only conservative management. In our study, 35 of 38 horses raced after surgery (92%), and 33 horses (87%) started more than five races, but tendonitis recurred in six horses.¹¹ Using a strict definition of success, 71% of horses started five or more times after surgery without recurrence of tendonitis, median earnings per start decreased significantly, and mean time from surgery to first start was 237 days. Suspensory desmitis developed in five horses, all of which had bilateral transection of the ALSDF.¹¹ In a similar study, 82% of STB horses raced after transection of the ALSDF, and 69% competed in five or more starts. In that study, horses that raced before injury had a better prognosis.⁵ Published results of conservative management in STB racehorses are scant, but in one retrospective study, 31 (76%) of 41 STB racehorses completed two races and started a third, but tendonitis recurred in 43% of these horses.¹²

In summary, transection of the ALSDF is clearly beneficial in the STB racehorse. Results of transection of the ALSDF in other types of sports horses have not been published, but I suspect hunters, jumpers, event, and dressage horses have a prognosis somewhere between those published for TB and STB racehorses. Unpublished results in the Three Day Event horse suggest that transection of the ALSDF may be of limited value, although reasons for this are not known.¹³ In a study of 33 horses in which 22 were nonracehorses, tendon splitting under ultrasonographic guidance, combined in some horses with transection of the ALSDF, resulted in a 68% return to previous level of competition.¹⁴ In the TB racehorse, results of transection of the ALSDF may be superior to those achieved with intratendonous injections and uncontrolled rehabilitation but are not as favorable as conservative management with controlled exercise.

Surgical Procedure

Currently I prefer conventional surgery using a transthecal approach through the flexor carpi radialis tendon sheath.³ Compared with the original description of transection of the ALSDF, this modified approach allows the surgeon to close the incision in three layers, providing a much more secure closure. Transection of the ALSDF is performed in a caudal location where the ligament is well defined. The surgical procedure is performed using a medial approach, with the horse in lateral recumbency (repositioned if bilateral transection of the ALSDF is performed) without tourniquet application. The initial incision is made directly over or just cranial to the cephalic vein. The vein is carefully dissected free from underlying antebrachial fascia and retracted caudally. The cranial approach to the vein is less vascular than is the caudal approach, and in most horses a vein penetrating the antebrachial fascia is clamped and ligated. It is important to sever the ALSDF completely, because incomplete division does not allow immediate transfer of load to the muscle. Intuitively, with incomplete division, it is likely that the ALSDF would heal faster after surgery and there is less likelihood that the ligament would heal in an elongated fashion. To sever the ligament completely, careful dissection of the proximal fibers from the nutrient artery and vein often is necessary, and in some horses these structures are cut inadvertently or division is

necessary. Division of the vessels causes no known clinical problem, but the vessel ends should be ligated to prevent edema and seroma formation.

Often the proximal aspect of the carpal canal is penetrated, because the ALSDF is attached to this structure distally. In horses undergoing transection of the ALSDF an occasional complication is inadvertent transection of the nutrient artery. Ligation of the vessel ends has no adverse clinical consequence. Complications with the surgical procedure are unusual, but the clinician should be aware of what normal healing of the surgical site entails. Nearly all sites develop diffuse swelling within 1 to 3 days after surgery, and in some horses hematoma or seroma formation occurs. The medial antebrachial region is highly vascular, and swelling is common and expected. If necessary, fluid can be evacuated, but this is seldom necessary. Firm, fibrous tissue forms at the surgical site by 4 to 6 weeks after surgery and may persist for several months. However, in most horses it is difficult to see residual swelling by 6 to 8 months after surgery, and cosmetic appearance is acceptable, if not normal, thereafter. I do not believe the postoperative morbidity associated with transection of the ALSDF is sufficient to warrant a change to the tenoscopic approach.

Transection of the ALSDF can be accomplished using an endoscopic (tenoscopic) approach through the carpal sheath. Both tenoscopic portals are made on the lateral aspect of the limb. Positioning a horse in lateral recumbency is preferred, but the surgical procedure can be done with the horse in dorsal recumbency if bilateral transection of the ALSDF is necessary.¹⁵ The ALSDF can be seen through the sheath and severed, but problems with hemorrhage from transection of the nutrient vessel can be encountered, and whether the entire ligament has been transected is sometimes unclear. Some surgeons prefer the endoscopic approach to avoid swelling that occurs with conventional surgery, but I feel this concern is overrated. Although this approach may be considered more elegant than conventional surgery, I prefer the conventional approach described previously.

How Transection Works

Originally, transection of the ALSDF was thought to reduce tendon strain, thereby reducing the risk of recurrence of tendonitis. If a gap remained in the ALSDF after transection, one could reasonably assume load was transferred to the SDF muscle. In this case the muscle rather than the inelastic scar within the tendon could stretch, thereby protecting the healed portion of tendon. Experimental evidence in cadaver specimens suggests that after transection of the ALSDF, load is transferred immediately to the muscle, but tendon strain increases because of a decrease in the metacarpophalangeal joint angle (hyperextension).¹⁶ Significantly increased strains in both the SDF and the suspensory ligament were measured in equine cadaver limbs after transection of the ALSDF in another study, and significant changes in metacarpophalangeal and carpal joint angles had occurred.¹⁷ Both of these studies were performed using cadaver limbs and in vivo results are unknown. Increased tendon strain after transection of the ALSDF may promote optimal tendon remodeling and collagen cross-linking. It has been proposed that the ALSDF likely heals after transection, but in an elongated fashion, allowing increased length of the bone-ligament-tendon-bone

axis, rather than replacing this load-bearing axis with muscle. This in theory would increase elastic limit of the damaged tendon and negate the intrinsic loss of elasticity found in healed but scarred tendon.⁵ I was initially skeptical of the mechanical effects of transection of the ALSDFT, but immediately after surgery horses may exhibit back-at-the-knee conformation (calf knee). Circumstantially the fact that suspensory desmitis and changes in carpal angle occur in horses after transection of the ALSDFT implicates a shift in distribution of load from the SDFT to the suspensory ligament.^{10,11} These clinical observations were reinforced with data from the experimental study using cadaver limbs in which increase strain in the suspensory ligament and changes in joint angles were confirmed.¹⁷ Although suspensory desmitis is a serious soft tissue injury and possibility of suspensory injury has altered recommendations for transection of the ALSDFT, I do not consider the risk of suspensory desmitis after surgery a reason to abandon the procedure either in racehorses or in other, nonracehorse sports horses. Based mostly on clinical impression I believe transection of the ALSDFT applies the time-honored principles of decompression, reduced load (increased strain), and protection of the inelastic scar achieved during reparative healing.

When Transection Should Be Performed

I used to perform transection of the ALSDFT with the assumption that the procedure was useful in preventing recurrence of tendonitis, and no attempt was made to perform surgery immediately after discovery of tendonitis. However, my current recommendation is that the procedure be performed as early as possible after injury. Obvious, visible reduction in tendon size occurs in the first 5 to 10 days after surgery, and although I cannot substantiate this claim, the procedure may be important in limiting or reducing inflammation and thus may improve the quality of early healing. Immediate reduction of load on the damaged tendon may explain decreased swelling, but possibly transection of the ALSDFT may function to decompress the injured tendon or may alter blood flow. Reduction in tendon swelling is most marked in horses undergoing transection of the ALSDFT and palmar annular desmotomy but occurs in those undergoing ALSDFT desmotomy alone. Ultrasonographic examination as early as 3 to 4 weeks after surgery often reveals marked improvement of anechoic or hypoechoic regions and reduced CSA measurements that compare favorably with those shown by others recommending intralesional injection of various products aimed at stimulating reparative or regenerative healing of the SDFT (Figure 69-8).

Horse Selection for Transection

Racehorses with mild, diffuse tendonitis or those with core lesions involving 10% or less of the CSA of the tendon likely will heal with conservative management and generally are not considered surgical candidates unless injury is recurrent. Racehorses with recurrent diffuse tendonitis, severe diffuse tendonitis, or core lesions involving 10% to 15% or more of the CSA of the tendon are surgical candidates. In other sports horses, transection of the ALSDFT is recommended in the affected limb in upper-level performance horses using similar guidelines as racehorses, but in lower-level horses conservative management of more severe injuries is often successful.

Fig. 69-8 • Transverse (left) and longitudinal ultrasonographic images at 21 cm distal to the accessory carpal bone of the right front superficial digital flexor tendon (SDFT) of a 4-year-old Standardbred mare, pacer, with severe superficial digital flexor tendonitis before (A) and 28 days after (B) transection of the accessory ligament of the SDFT and palmar annular desmotomy. There is marked improvement in the echogenicity of the SDFT soon after surgery, confirming the observation that the clinical appearance of the tendon improves quickly after surgical management.

Bilateral Transection

Bramlage's early results using transection of the ALSDFT in TB racehorses were complicated by the development of SDF tendonitis in the contralateral limb.^{2,3} In any racehorse, bilateral tendonitis is not uncommon. Ultrasonographic evaluation of young racehorses with obvious tendonitis in one limb often reveals mild tendonitis in the contralateral limb, and I suggest that both limbs be examined carefully before surgery. These facts led me to consider performing transection of the ALSDFT in racehorses bilaterally, even when the procedure was done prophylactically. However, the horse's age, existence of concomitant suspensory desmitis in the contralateral limb, gait (in STB racehorses), type of sports horse, and cause of tendonitis play a role in decision making. Bilateral transection of the ALSDFT is recommended in horses with bilateral tendonitis; in young, unproven (unraced or early in training) 2- or 3-year-old TB or STB racehorses with unilateral tendonitis in which the contralateral limb is operated on prophylactically; and in horses with subtle ultrasonographic evidence of contralateral tendonitis. Unilateral transection of the ALSDFT (surgical procedure performed in affected limb only) is recommended in show horses; in young racehorses,

particularly STB racehorses with suspensory desmitis in the contralateral limb; and in horses with tendonitis caused by direct trauma (tendonitis is unlikely to occur in the contralateral limb), such as a bandage bow. In older TB and STB racehorses I most often recommend transection of the ALSDF in the affected limb only. In STBs, pacers are more likely than trotters to develop contralateral tendonitis, so in young, unproven pacers I will likely recommend bilateral transection more often than in trotters. In older, proven pacers, I recommend transection only in the affected limb.

Aftercare

Horses are given 2 weeks of absolute stall rest, followed by 6 weeks of stall rest with an increasing handwalking program, beginning with 10 to 15 minutes twice daily. After 8 weeks, an additional handwalking program, walking in the jog cart (STB racehorses), or swimming physiotherapy is recommended for an additional 8 weeks. Turnout exercise is not permitted. Horses then are placed back into early training by trotting and light galloping (TBs) or by walking and light jogging (STBs). Serial ultrasonographic examinations should be performed each time an incremental increase in exercise is planned or when clinical evidence of mild inflammation exists. Time to first start varies considerably but in TB and STB racehorses is 11 to 12 months and 8 to 9 months, respectively.

Large, full-limb support bandages are considered important in limiting motion and swelling at the surgical site(s) and are maintained and changed as needed for a minimum of 14 days. Once bandages have been removed, swelling inevitably occurs at the site(s) of transection of the ALSDF. An inner, lighter bandage is covered by a heavy cotton, full-limb dressing. Concomitant systemic use of PSGAGs or hyaluronan is controversial, and clear benefits have not been demonstrated, but the use of these medications makes sense to me theoretically. Eight weekly injections of PSGAGs are recommended. Dramatic clinical improvement in tendon size occurs when transection of the ALSDF is combined with other surgical procedures (see Figure 69-8) or in horses in which peritendinous injection of corticosteroids or a combination of corticosteroids and other anti-inflammatory products is used adjunctively with surgery. Phenylbutazone (4.4 mg/kg, intravenously or orally [PO], twice daily for 10 to 14 days) administration appears useful in reducing swelling and improving comfort after surgery.

PALMAR ANNULAR DESMOTOMY

Much attention has been given to transection of the ALSDF and to tendon splitting, but little to no recent mention has been made of palmar annular desmotomy. This procedure remains a most useful surgical treatment, usually combined with transection of the ALSDF, to manage tendonitis of the distal aspect of the SDF. Two distinct clinical situations occur in which palmar annular desmotomy is recommended. The most successful is adjunct use of palmar annular desmotomy in horses with SDF tendonitis. The PAL is a passenger in the disease process, which results in annular constriction of the SDF. As the SDF enlarges, the PAL impedes gliding function of the tendon. Further tendon enlargement and inflammation may cause thickening of the PAL, but the primary

disease process involves the SDF, not the PAL or DFTS. The PAL often becomes thickened and adheres to underlying DFTS and SDF. Once the PAL impedes SDF function, lameness, continued swelling, and inflammation occur. Palmar annular desmotomy usually is combined with transection of the ALSDF but can be a career-saving procedure when done alone. Palmar annular desmotomy provides immediate decompression and improved gliding function of the SDF, which are important, time-honored surgical principles to follow. The decision to transect the PAL is based on clinical observations. Typically a notch appears along the palmar aspect of the limb when viewed from the side, at the location of the PAL. Even if impingement is not severe, I recommend palmar annular desmotomy. Viewed with ultrasonography the PAL may be normal to moderately thickened and adhesions may exist, but actual evidence of PAL desmitis is lacking. The SDF is abnormal. After palmar annular desmotomy a reduction in tendon size is seen within 5 to 10 days, and clinically initial swelling appears to redistribute proximal to the PAL and distal to the level of the surgical site. The PAL likely reforms in an elongated fashion after surgery but well after tendon size has decreased. Adhesion formation between the PAL, DFTS, and SDF may occur after surgery, and inadvertent damage to the edge of the SDF is possible, but the benefits appear to outweigh the risks of the procedure.

The second and less successful clinical situation in which palmar annular desmotomy is used is in horses with chronic tenosynovitis without tendonitis of the SDF. These horses may have primary tendonitis of the DDF, injury of the manica flexoria, or rarely primary palmar annular desmitis (see Chapter 74).

I prefer a minimally invasive conventional surgical approach. A 1.5-cm stab incision is made medially (when used with transection of the ALSDF) just proximal to the PAL through skin, subcutaneous tissues, and DFTS, but care should be taken to avoid incision of the medial (lateral) aspect of the SDF. In horses with chronic, severe tendonitis the tissue can be quite thick and care must be taken not to incise the underlying SDF. A curved bistoury (Sontec Instruments, Englewood, Colorado, United States) or one blade of a pair of straight Mayo scissors is inserted deep to the PAL, superficial to the SDF. The PAL is incised in its entirety, and care must be taken to transect the distal aspect completely. Reversing the bistoury or scissors blade and transecting the remaining fibers of the PAL and thickened DFTS proximal to the incision may be necessary. The small incision then is closed using subcutaneous and skin sutures. Occasionally a larger incision is necessary in horses with severe and chronic tendonitis, because adhesions preclude accurate insertion of the bistoury or scissors. Care after surgery is the same as described for transection of the ALSDF when the procedures are done simultaneously, but if palmar annular desmotomy is performed alone, an accelerated exercise program often is advised. Long stall rest periods after palmar annular desmotomy may promote earlier healing of the severed PAL and adhesion formation. After an initial 2-week period of stall rest, handwalking is undertaken for 2 weeks and the tendon is reevaluated. Acceleration of the exercise program at this point may be recommended depending on factors such as the horse's value, class of racing, time of season, and owner's and trainer's proposed schedule.

Other surgical approaches, including an extended open approach or an open approach without entering the DFTS, have been described, but I do not recommend them. The approach described previously can be done with horses in the standing position or while they are under general anesthesia. Endoscopic examination of the DFTS and transection of the PAL have been described elegantly (see Chapters 24 and 74).¹⁸ This is a novel visually pleasing surgical procedure, but in my hospital it is expensive and time-consuming to perform. Complications with any approach include incisional dehiscence, delayed healing, infection, and damage to the ipsilateral edge of the SDFT. Horses with severe tendonitis in which the SDFT is severely enlarged and those with extensive adhesions and thickening of the PAL and DFTS are at greatest risk for complications.

TENOSCOPY OF THE DIGITAL FLEXOR TENDON SHEATH AND CARPAL SHEATH

See Chapter 24 for additional discussion of tenoscopy of the DFTS and carpal sheath. I perform tenoscopy of the DFTS for management of tenosynovitis primarily in non-racehorses and most commonly in the hindlimb. Tenoscopy is valuable for validation of ultrasonographic findings, to evaluate the surfaces and debride defects in the flexor tendons, to debride tears in the manica flexoria, to remove the manica flexoria in horses with complete tears of the structure, to remove soft tissue masses and perform adhesiolysis, and to perform palmar or plantar annular desmotomy under endoscopic guidance. Carpal tenoscopy is valuable to perform ostectomy of the distal caudal aspect of the radius in horses with the unusual condition of exostosis of the distal caudal aspect of the radius and accompanying tenosynovitis, to remove supracarpal exostoses, and to inspect and debride lesions associated with the flexor tendons and the ALSDF. Occasionally a trotter develops acute tenosynovitis and lameness as a result of hemorrhage in the carpal sheath, and careful ultrasonographic examination reveals injury to the ALSDF. Desmitis of the ALSDF has been reported in trotters and nonracehorses and was managed conservatively.¹⁹ However, tenoscopic examination provides additional information about the soft tissue structures and extent of injury, and, importantly the torn edges of the ALSDF can be debrided.

PROXIMAL METACARPAL FASCIOTOMY AND CARPAL RETINACULAR RELEASE

For horses with proximally located SDF tendonitis an effective method to decompress the damaged, enlarged SDFT and improve gliding function is to transect the proximal metacarpal fascia and carpal retinaculum (desmotomy, retinaculotomy). Clinical diagnosis in horses with only proximal SDF tendonitis can be challenging because swelling and pain can be easily missed during palpation. Lameness is often inappropriately severe based on the minimal clinical signs present; horses often stand with an over-at-the-knee conformation (bucked knee), a positive response to carpal flexion is manifested, and horses may have mild

carpal tenosynovitis. Lameness may worsen after palmar digital analgesia, a clinical observation most commonly seen in horses with proximal palmar metacarpal and palmar carpal region pain. Horses with proximal SDF tendonitis have been reported to have a poor prognosis (two of 12 horses returned to full work).²⁰ My experience with conservative management appears to be somewhat better than in this publication, but I believe surgical management offers the best chance for full recovery.²¹ Horses with severe mid-to-distal SDF tendonitis may have proximal involvement, and fasciotomy or carpal retinacular release appears beneficial. Old horses with inexplicably severe SDF tendonitis often have extension of tendonitis to the region of the carpal canal and may have moderate to severe carpal tenosynovitis (see discussion on page 707). Carpal retinacular release is described for use in horses with carpal tenosynovitis, but it can be useful in horses with SDF tendonitis in which transection of the metacarpal fascia is done concomitantly. This procedure most often is performed in combination with transection of the ALSDF but can be combined with palmar annular desmotomy also. Prognosis in horses with SDF tendonitis in which transection of the ALSDF and fasciotomy or carpal retinacular release are performed is guarded to good. Prognosis in old horses requiring transection of the ALSDF, fasciotomy or carpal retinacular release, or, in some, palmar annular desmotomy is better than expected, because swelling and lameness are often severe in these horses. Substantial reduction in tendon size and lameness score after surgery can be expected, and some horses have returned to light riding or field hunting.

Fasciotomy or carpal retinacular release is done using conventional surgical techniques and usually via a medial approach, because the procedure often is combined with transection of the ALSDF (Figure 69-9). To perform fasciotomy alone a 2- to 3-cm incision is made through skin and subcutaneous tissues just dorsal to the cephalic vein at the level of the proximal aspect of the second metacarpal bone. Because underlying tendonitis is present, bleeding can be excessive. A 1-cm incision is made in the dense, underlying metacarpal fascia, and straight Mayo scissors are used to extend the fasciotomy proximally through distal aspect of the carpal retinaculum to the level of the distal aspect of the accessory carpal bone and distally to the midmetacarpal region. No distinction is perceivable between fascia and retinaculum because the tissues blend together. Complete transection of the carpal retinaculum is often necessary and requires tedious dissection and careful ligation of vessels. The radial artery and vein run between the inner and outer lamina of the carpal retinaculum and care must be taken to avoid severing these vascular structures. It is mandatory to sever both the inner and outer lamina of the carpal retinaculum to provide decompression and improved gliding function of the SDFT (see Figure 69-9). I prefer using conventional surgical techniques but tenoscopic approaches exist. Conventional surgical incisions often are quite long since it is necessary to sever the carpal retinaculum to the level of the proximal aspect of the accessory carpal bone. Subcutaneous tissues and skin are closed routinely. Bandaging and care after surgery are the same as for transection of the ALSDF because the procedures usually are performed in combination.

Fig. 69-9 • A, Intraoperative photograph (taken from a palmar perspective) of a 5-year-old Standardbred stallion, pacer, with pronounced lameness from tendonitis of the proximal aspect of the left front superficial digital flexor tendon (SDFT; distal is to the right and dorsal is to the top). The horse is positioned in left lateral recumbency under general anesthesia, and desmotomy of the medial metacarpal fascia (fasciotomy) and carpal retinaculum is underway. The thick, outer lamina of the carpal retinaculum (*black arrows*) is an extension of the metacarpal fascia that has been cut, but it is important to completely sever the inner lamina (*white arrowheads on top of Metzenbaum scissors*) that encircles and constricts the swollen SDFT. **B,** Intraoperative photograph (taken from a palmar perspective) of the same horse after metacarpal fasciotomy and desmotomy of the carpal retinaculum showing that the enlarged SDFT is now decompressed, expanding the cut edges of the severed fibrous tissue (*double-headed arrow*). This horse raced successfully after surgery.

TENOPLASTY—TENDON SPLITTING

Interest in tendon splitting as an adjunct method to manage SDF tendonitis has been renewed. Originally the procedure was developed to promote vascularization of the tendon in horses with chronic tendonitis, and early results showed promise.²² Experimental studies questioned the value of tendon splitting, and the conclusion was that splitting induced excessive granulation tissue and slow healing of areas of tendon necrosis.^{23,24} Clinical use of the technique then fell out of favor, but renewed interest was sparked by reports of combined use of splitting with transection of the ALSDF in a clinical study and improved healing and revascularization of acute collagenase-induced tendon injuries in an experimental study.^{25,26} The collagenase model produces severe tendonitis with extensive necrosis, and I question the value of this model in mimicking the naturally occurring disease. Various authors have reported clinical experiences with tendon splitting used with other procedures, but clinical studies using splitting alone are lacking.^{4,5,11,14} Tendon splitting currently is used in horses

with core lesions early in the disease process rather than in horses with chronic tendonitis, the group for which the procedure was designed originally. Tendon splitting, done to decompress areas of hemorrhage, or to provide vascular access channels early after injury, makes theoretical sense for horses with anechoic lesions, but it is of questionable value if done once granulation tissue has formed or mature collagen fibers exist. The rationale given for use in early lesions is to decompress the area of hemorrhage and to provide vascular access channels to improve vascularization by vessel ingrowth. Soon after injury areas of hemorrhage become granulation tissue in which the value of decompression would be minimal. The surgical procedure would have to be performed before granulation tissue develops (3 to 5 days, but certainly before 2 weeks) and may be best reserved for horses with anechoic lesions. Damage caused to peritendinous tissues and surrounding intact tendon fibers must be considered and may outweigh any benefit. However, the procedure has been done apparently successfully or at least without outward harmful effects.

In clinical practice I use the procedure when requested by referring veterinarians or in TB racehorses with anechoic or hypoechoic core lesions. In fact, my best results in TB racehorses have been achieved using tenoplasty in combination with transection of the ALSDF (see [Figure 69-1](#)). The percutaneous technique is preferred, and using a double-edged tenotome is recommended. The procedure seldom is used in the STB racehorse, and in our report detailing results of transection of the ALSDF in this racing breed, tendon splitting was done in only one horse.¹¹ In STB racehorses managed with transection of the ALSDF, I often recommend palmar annular desmotomy if tendonitis extends to the distal metacarpal region, but seldom recommend tenoplasty. In the STB racehorse, I will consider tenoplasty in horses with lesions involving the lateral aspect of the SDFT. Currently I recommend that tenoplasty be done in TB racehorses or other non-STB sports horses with transection of the ALSDF. Needle decompression of anechoic lesions early after injury may make theoretical sense to provide early decompression, but creation of vascular access channels using this method appears implausible and I do not use the technique.

COMBINED SURGICAL PROCEDURES

Because SDF tendonitis is career-limiting in many sports horses, early and aggressive surgical management should be considered. Potentially, injection of growth factors, MSCs, fresh liquid bone marrow or bone marrow concentrate, or other substances used with surgery and strict rehabilitation may offer the best hope for a successful outcome. Combined surgical management using transection of the ALSDF and palmar annular desmotomy; transection of the ALSDF, annular desmotomy, and fasciotomy or carpal retinacular release; or in some horses various combinations with tenoplasty has been successful even in horses with severe tendonitis. In my experience, using transection of the ALSDF without palmar annular desmotomy in horses with distal SDF tendonitis often results in failure, as does using transection of the ALSDF without fasciotomy or carpal retinacular release in those with lesions involving the proximal aspect of the SDFT.

The ideal management program for horses with SDF tendonitis has yet to be discovered but should rely on the principles of tendon healing, including minimizing peritendinous scar tissue formation, minimizing the effect of hemorrhage and subsequent granulation tissue formation and disorganized fiber alignment, maximizing gliding function within and external to the SDFT, reducing load and protecting inelastic scar tissue by increasing the length of the bone-ligament-tendon-bone construct, and using an exercise regimen that allows healing and maturation of collagen fibers without deleterious effects of uncontrolled exercise. Surgical management preserves many of these time-honored principles and has proved useful in many types of sports horses.

Treatment of tendon injuries in racehorses is a challenge to clinicians and researchers. Return to racing is associated with a high rate of recurrent injury. However, much progress has been made in the past two decades in diagnostic identification and classification of injury, and the biochemical and biomechanical aspects of tendon injury. Treatment and management programs by necessity depend heavily on economics and trainer decisions relative to continued exercise or long-term rehabilitation. Of vital importance are accurate injury severity categorization, controlled exercise in long-term rehabilitation programs, and ultrasonographic monitoring at all levels of treatment. Improved athletic outcome results gradually evolve as continued basic science research and clinical investigations of past and proposed therapeutic regimens unfold.

▣ SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN EVENT HORSES, SHOW JUMPERS, DRESSAGE HORSES, AND PLEASURE HORSES

Sue J. Dyson

SDF tendonitis is a potentially career-limiting injury in event horses and Grand Prix-level show jumpers. Although the incidence of SDF tendonitis is much lower in dressage horses, it is also an important injury. The clinical manifestations vary considerably.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN EVENT HORSES

Clinical Signs

Although all event horses are at risk for injury of the SDFT, the incidence of injury is highest in horses competing at advanced or international level, especially those competing in Three Day Events.^{1,2} This is probably because of the combination of galloping long distances and jumping on very variable terrain and footing. The introduction of short format Three Day Events does not appear to have reduced the risk of injury. After training or competing, riders commonly apply a proprietary clay to the forelimbs and bandage the limbs at least overnight. This practice may result in early warning signs of impending tendon damage being missed. Because lesions frequently occur bilaterally, subtle changes in limb temperature may be missed except by the most astute and vigilant riders or grooms.

The clinical signs associated with tendon damage vary markedly. A horse may pull up lame after the cross-country phase of an event and rapidly develop peritendinous soft tissue swelling and pain on palpation of the tendon. In some horses the degree of pain is severe and the horse may be distressed and reluctant to bear weight on the limb. If lesions occur bilaterally, the horse may be reluctant to move and its behavior may mimic that of a horse that is tying up. These horses may require both analgesia and sedation to relieve the distress. Clinicians should be aware that a horse may appear very lame, but it may not be possible to elicit pain by palpation of the tendon, although the tendon may feel abnormally soft.

In contrast, a horse may complete the cross-country phase and appear sound, with lameness developing several hours later. Although soft tissue swelling may develop, in some horses there may be absolutely no clues as to the cause of lameness (i.e., no heat, pain, or swelling). This may persist for many days, and then suddenly enlargement, subtle or obvious, of the SDFT may be seen despite resolution of lameness. If swelling is subtle, it may be overlooked and only recognized after localization of the pain causing lameness by local analgesic techniques and clipping of the limb in preparation for ultrasonographic evaluation.

In other horses, lameness is never present. The horse initially may exhibit poor performance, and clinical examination may reveal that the SDFTs are slightly enlarged. Alternatively, the horse may have localized heat and pain on pressure applied to the SDFT, with no history of lameness. Some horses have obvious clinical signs of SDF tendonitis after the first training gallop, cross-country schooling, first event, or a period of reduced work for some months after a Three Day Event. It seems highly likely that these horses sustained damage to the SDFT(s) at the Three Day Event without associated detectable clinical signs.

Clinical signs and the severity of the tendon injury are not necessarily correlated. The clinical signs of SDF tendonitis can easily be masked. I have examined a number of horses at events when the horses have finished lame and had clinical signs compatible with SDF tendonitis. The horses were treated by application of a modified Robert Jones bandage and systemic NSAIDs. Ultrasonographic examination after 5 to 7 days was recommended. The horses were then examined by the owners' regular veterinary surgeons, who were unable to detect any palpable abnormality after removal of the bandage and therefore elected not to perform an ultrasonographic examination. Return to work was recommended by the second veterinary surgeons with catastrophic consequences. Some horses that have completed the speed and endurance phase of a Three Day Event and sustained a tendon injury can be managed to pass the final horse inspection and complete the show jumping without marked deterioration of the tendon injury. In older horses (usually >12 years of age) lesions of the most proximal aspect of the SDFT may develop, extending into the carpal sheath.³ These can be quite difficult to palpate because heat is difficult to detect and the tight flexor retinaculum may conceal swelling, but they usually cause lameness. The lameness is variable in severity and may be inapparent following rest for several days, but recurs after fast work. Lameness is frequently accentuated by carpal flexion. Lameness may be improved by palmar and

palmar metacarpal nerve blocks, but median and ulnar nerve blocks are sometimes required to abolish lameness.

SDFT injury can also arise after an overreach injury; there may also be damage to other structures. The effects of local trauma can vary from localized peritendinous edema with no evidence of tendon damage, to localized hypoechoic or anechoic lesions on the palmar aspect of the SDFT (the result of blunt trauma), to partial or complete laceration (see Chapter 81). Local traumatic injuries do not extend far proximodistally, but partial lacerations can be associated with the development of longitudinal splits extending proximally or distally, which are the result of altered shear stresses. Careful ultrasonographic examination of all adjacent structures is important to establish the severity of injury, bearing in mind that the site of a skin abrasion may not coincide with the site of tendon injury. The subsequent development of peritendinous fibrosis may influence the prognosis.

Diagnostic Ultrasonography

In my opinion, whenever unexplained lameness occurs in an event horse, the SDFTs should be examined ultrasonographically. I also recommend routine ultrasonographic examination 10 to 14 days after the horse has completed a Three Day Event. Baseline ultrasonographic images should be available for comparison, with measurements of CSA at 4-cm intervals distal to the accessory carpal bone throughout the metacarpal region (Figure 69-10). Mild asymptomatic lesions may be identified and should be monitored serially. Ultrasonographic examination should be mandatory for any horse with a history of slight heat or filling in the metacarpal region unless there is an obvious cause (see Figure 69-6). However, it is equally important to recognize

the constraints of ultrasonographic examinations from both the skill of the veterinarian and the limitations of the resolution of ultrasonographic images. If an SDFT appears normal ultrasonographically but the clinical signs raise suspicion of injury, the horse should be treated as if it has a tendon injury, with repeat examination after a further 7 to 14 days.

In horses with early subtle tendonitis the only abnormality detectable may be slight, localized enlargement in CSA of the tendon; therefore area measurements and comparisons with the contralateral limb can be extremely valuable. If the injury is bilateral, subtle enlargement in both SDFTs is easily missed. It is important to examine the relative sizes of the SDFT and DDFT and to be aware of the way in which a normal SDFT changes shape from proximally to distally in the metacarpal region (see Chapter 16).

It is also important to look carefully at the echogenicity of the SDFT and compare it with the DDFT and more proximal and distal sites within the SDFT. Subtle lesions often result in a slight diffuse reduction in echogenicity of part or all of the CSA of the tendon, but only in a localized region. Such lesions are easily missed, especially if the gain controls of the ultrasound machine are set too high or if the limb is examined without fine clipping of the hair coat. Detection of these early injuries is very important, because a horse can make a relatively rapid complete recovery at this stage, whereas continued work may result in a much more severe, career-limiting injury. In these early injuries, longitudinal images of the tendon often appear normal. Both forelimbs should be examined routinely.

Because lesions may be very localized, it is important to carefully and systematically examine the tendon from proximally to distally. Although gross core lesions of the

Fig. 69-10 • A, Transverse ultrasonographic image of the palmar aspect of the right forelimb of a 9-year-old advanced event horse; the scan was obtained at 17 cm distal to the accessory carpal bone. Medial is to the left. The horse initially had slight heat in the metacarpal region but no lameness. The superficial digital flexor tendon is enlarged (cross-sectional area 1.2 cm^2), and there are focal anechoic regions on the lateral border. The lesion extended from 14 to 20 cm distal to the accessory carpal bone. **B**, Lateral parasagittal ultrasonographic image of zone 2B; proximal is to the left. There is some loss of long linear echoes, with an anechoic lesion on the palmar aspect.

SDFT are relatively easily identified without fine clipping of the hair coat, image resolution is inferior. Application of mineral oil helps to improve resolution, but this can destroy the ultrasound standoff pad. Subtle lesions will be missed unless the hair is clipped, although shaving is unnecessary. Owners may be reluctant to allow the limbs to be clipped, suggesting that this may jeopardize the horse's evaluation at an inspection at a forthcoming Three Day Event if the limbs actually appear normal and the horse is able to compete. Owners must be persuaded that it may be essential to clip the limbs and that only a narrow strip is necessary; the clinician should suggest that if the horse is fit to compete, the entire horse should then be clipped.

Treatment

Management of SDF tendonitis in the event horse is difficult. Individual horses' capacities to recover from tendon injuries vary considerably. In some horses a marked improvement is seen in the clinical and ultrasonographic appearance of the tendon within 3 months of first injury, whereas little progress is seen in other horses with a similar injury. In almost all horses a convalescent period of 1 year after injury is required. In some horses, normal echogenicity is never restored, and a fairly obvious central hypoechoic area persists ultrasonographically. These horses may be able to withstand one day events but frequently sustain reinjury at a Three Day Event. Lesions in the distal one fourth of the metacarpal region (zones 3B and 3C) are particularly at risk for reinjury. Even in those horses in which relatively normal echogenicity is restored, it is relatively unusual for them to be able to complete more than two Three Day Events without reinjury unless the original injury was mild.

Most published studies of the treatment of SDF tendonitis relate to the racing TB and STB. It is generally accepted that the rate of reinjury is high, especially for horses competing in Three Day Events. Although a horse may be managed successfully to complete one Three Day Event after injury, the risk of subsequent injury is very high.

Of 23 event horses treated with a controlled exercise program alone, 57% were able to return to full athletic function without recurrent injury for a minimum of 2 years after resumption of full work,⁴ compared with 56% of 25 horses that received intralesional hyaluronan and the same controlled exercise program and 58% of 31 horses that received intralesional PSGAGs administered intralesionally, systemically, or by both routes. Almost all horses with a unilateral injury reinjured the same tendon. No horses completed more than two Three Day Events without recurrent injury.

The results of intralesional treatment with β -aminopropionitrile fumarate are similar if both the treated limb and the noninjured limb are considered.⁵ However, the reinjury rate in the treated limb was considerably better (16%). Of 22 advanced-level event horses, 14 have completed two to six Three Day Events, including nine that have completed three or more Three Day Events at championship level four-star FEI events without recurrent injury. An additional five horses completed two to five Three Day Events before injuring the contralateral limb; three of these horses have completed two additional four-star Three Day Events. Overall, in my experience this treatment seems to

offer the best long-term prognosis for event horses with moderate-to-severe injuries of the SDFT, although a licensed product is no longer available. After treatment, horses are walked for 30 to 60 minutes daily for 4 months and are then reexamined ultrasonographically. Successfully treated horses had a remarkably good strength of fiber pattern in longitudinal ultrasonographic images 4 months after treatment. This feature appears to be a good prognostic indicator. Work intensity is slowly and progressively increased thereafter, with horses generally reaching full work by 12 months after treatment. It is premature to judge the efficacy of stem cell therapy, but early results from 109 horses from all racehorse and sports horse disciplines showed a reinjury rate of 13% 1 year after resumption of work.⁶ My clinical experience with event horses has been less favorable, although some horses have responded extremely well with sustained return to full athletic function. More recent data from 83 flat racehorses and eight National Hunt racehorses (which excludes horses lost to follow-up) indicate a reinjury rate of 31% (flat racehorses 50%; National Hunt racehorses 23%) 2 years after resumption of full work.⁶ A problem remains with medical management, by whatever means, of a horse with a unilateral injury, with no detectable ultrasonographic lesion in the contralateral limb. There is no doubt that despite successful management of the injured limb, the noninjured limb is at risk of subsequent injury.

Desmotomy of the accessory ligament of the SDFT has been less successful in the management of SDFT lesions in event horses than in racehorses, and the disappointing results achieved in my clinic and elsewhere in the United Kingdom have led to this technique being abandoned. It has also fallen out of favor in the United States. Tendon splitting has been used for anechoic central core lesions, combined with a controlled exercise program, with successful results, but the number of treated horses does not compare with the studies described previously.

Regardless of the method of management, serial ultrasonographic examinations during the convalescent period seem to be the most accurate predictors of the final outcome. If the echogenicity and fiber pattern have improved markedly by 4 months after injury, then the longer-term prognosis is much better than in horses in which improvement is only slight. The strength of the fiber pattern when full work is resumed is a good predictor of whether the horse will sustain reinjury.^{4,5} It does appear that some horses have an innately better ability to repair tendon lesions than others. Use of Doppler ultrasonography can be helpful for monitoring repair and for identification of reinjury. Normal SDFTs usually have minimal discernible blood flow. After injury a vascular pattern is usually obvious and subsides 3 to 6 months after injury. Reappearance of blood flow indicates reinjury.

Horses with proximal lesions that extend into the carpal canal have generally responded poorly to conservative management, with a high rate of recurrent injury. Surgical release of the flexor retinaculum has enabled several horses to return to full athletic function. The results of treatment with intralesional MSCs have been disappointing.

Pastern Lesions

Injury to the medial or the lateral branch of the SDFT in the pastern region occurs most commonly in forelimbs but

also occasionally in hindlimbs (see Chapter 82). Such injury can occur as an isolated acute lesion or as a sequela to previous tendonitis in the metacarpal region. There is usually acute-onset, moderate lameness. In some horses, soft tissue swelling is immediately apparent on the palmar aspect of the pastern, but in others, obvious swelling may take several days to develop. In these horses, perineural analgesia may be required in the acute stage to localize the source of pain. Lameness is alleviated by perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones. Diagnosis is confirmed ultrasonographically. The affected branch is usually enlarged, with poor demarcation of its margins and diffuse or focal areas of reduced echogenicity. There may be some peritendinous hyperechogenic tissue representing fibrosis. Horses with acute lesions with no preceding tendonitis have a fair prognosis for complete recovery after adequate rest for at least 6 months. However, horses with lesions secondary to tendonitis in the metacarpal region have a more guarded prognosis.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN SHOW JUMPERS

Injury to the SDFT is comparatively unusual in show jumping horses, except either those competing at international

level,^{1,7} or horses approximately 15 years of age or older. Injury to the SDFT is most commonly unilateral. There are six typical manifestations:

1. Insidious-onset peritendinous swelling and enlargement of the SDFT, but no associated lameness (Figure 69-11, A). Such horses can generally be managed, but if maintained in full work it is likely that the lesion will deteriorate.
2. Sudden onset of severe lameness while jumping, with rapid development of heat, pain, or swelling. In some horses this is a sequela to previous low-grade injury, but in others there were no previous warning signs. Injuries occur most frequently during competition and may result in an acute, severe lameness with the horse abruptly stopping during a round. Alternatively, the horse may finish lame.
3. Sudden-onset lameness in an older horse, with a lesion extending into the carpal sheath.
4. Sudden-onset lameness associated with distention of the DFTs. There may be no palpable abnormality of the digital flexor tendons, but ultrasonography will reveal a marginal lesion of the SDFT.
5. Progressive enlargement of the SDFT after a previous injury of the accessory ligament of the DDFT (ALDDFT) and lameness. There is usually adhesion formation between the SDFT and the ALDDFT.

Fig. 69-11 • A, Transverse ultrasonographic image of the palmar aspect of the left forelimb of a 13-year-old Grand Prix show jumper; the image was obtained at 11 cm distal to the accessory carpal bone. The horse initially had localized heat and swelling but no lameness. A focal hypoechoic lesion is seen on the palmar margin of the superficial digital flexor tendon (SDFT). The lesion extended less than 1 cm proximodistally. The horse's condition was managed symptomatically, and the horse continued to compete successfully for 6 months with no change in the lesion; the horse then developed acute lameness with exacerbation of the injury. **B**, Transverse ultrasonographic image of the palmar aspect of the distal metacarpal region of a 14-year-old Grand Prix show jumper with acute-onset, severe lameness associated with distention of the digital flexor tendon sheath. Medial is to the left. The medial aspect of the SDFT is enlarged, its margin is irregular, and there are focal anechoic lesions.

6. Occasionally, traumatic injuries occur to the SDFT within the carpal sheath after the horse has sustained a fall (see Chapter 75).

Injuries restricted to the proximal one third of the metacarpal region are common, and there appears to be a tendency for the development of peritendinous adhesions and recurrent lameness. Horses with these lesions have been difficult to manage successfully, as are those with lesions that extend proximally into the carpal canal. However, horses with lesions restricted to the metacarpal region, without peritendinous adhesions, can be rehabilitated and returned to competition with judicious, symptomatic management relatively quickly compared with event horses with a comparable injury. Some horses can withstand return to full work despite persistence of quite obvious ultrasonographic abnormalities of the SDFT. However, the tendon must be monitored carefully, because some horses continue to sustain recurrent low-grade injuries, which result in the tendon becoming progressively larger and wrapping around the DDFT and becoming contiguous with the ALDDFT. Severe injuries predispose to the development of secondary desmitis of the ALDDFT (see Chapter 71).

Desmitis of the ALDDFT may occur as a primary lesion. Severe lesions predispose to the development of secondary SDF tendonitis. Horses with these injuries are difficult to manage successfully. Marginal tears of the SDFT within the DFTS occur occasionally, manifesting as an acute-onset lameness associated with distention of the DFTS (see Figure 69-11, B).

Fourteen (93%) of 15 show jumpers with unilateral SDF tendonitis that were treated conservatively after a controlled exercise program were able to return to full athletic function for at least 2 years without recurrent injury, compared with four (80%) of five horses treated with intralesional hyaluronan and three (75%) of four horses treated with PSGAG.⁴ Five horses with severe lesions that had not responded adequately to conservative management were subsequently treated with β -aminopropionitrile fumarate, and all have withstood return to international competition without recurrent injury.⁵ Horses with lesions extending into the carpal canal have been treated by carpal retinacular release with variable results.

Older horses (>15 years of age) with SDT tendonitis generally have a more guarded prognosis. Some of these injuries appear to be progressive degenerative lesions, which deteriorate despite rest.³ Injury of the SDFT in ponies is unusual, but I have experience of several teenage event and show jumping ponies that have sustained injuries of the SDFT in the proximal metacarpal region extending into the carpal canal. Although these ponies had unilateral lameness, lesions were identified ultrasonographically bilaterally. Bilateral carpal retinacular release resulted in a favorable outcome.

SUPERFICIAL DIGITAL FLEXOR TENDONITIS IN DRESSAGE HORSES

SDF tendonitis is not a common injury in dressage horses, but it does occur occasionally (Figure 69-12). The

Fig. 69-12 • **A**, Transverse ultrasonographic image of the palmar aspect of the left forelimb of a 12-year-old Grand Prix dressage horse. The image was obtained at 22 cm distal to the accessory carpal bone; medial is to the left. The horse had exceptionally extravagant forelimb paces and acute-onset, moderate lameness. There is a focal hypoechoic lesion on the lateral aspect of the superficial digital flexor tendon (SDFT). The lesion extended from 16 to 26 cm distal to the accessory carpal bone. At this level the tendon is slightly enlarged (cross-sectional area 1.2 cm²), but at all other levels it was of normal size. **B**, Longitudinal ultrasonographic image of zone 3A obtained from the palmar midline; proximal is to the left. The SDFT appears normal.

Continued

Fig. 69-12, cont'd. • **C**, Longitudinal ultrasonographic image of zone 3A obtained from the palmarolateral aspect of the metacarpal region shows reduced echogenicity of the SDFT.

at-risk horses appear to be young, very extravagantly moving horses and older Grand Prix horses. Lesions are often quite focal, may be marginal, and are usually associated with low-level lameness. Most lesions occur in the forelimb, but lesions also occur in the distal metatarsal and pastern regions of hindlimbs. Lesions also occur in some relatively young horses disproportionate to the quality of their paces and work history, and these are often difficult to manage and may reflect primary degenerative lesions. Young, big-moving horses with low-grade lesions are managed by restriction to stall rest and controlled exercise, and horses usually resume work after resolution of localized heat, pain, and peritendinous swelling. Horses

with lesions in the proximal one third of the metacarpal region are much more difficult to manage, and clinical signs resolve very slowly regardless of the method of management. Hindlimb lesions have been restricted to the DFTS and are sometimes bilateral. They often are associated with adhesion formation within the DFTS and tend to result in chronic lameness.

Some marginal tears of the SDFT are recognized only during exploratory tenoscopy of a distended DFTS. Concurrent tears of the manica flexoria have also been identified during tenoscopic evaluation. The results of debridement of marginal tears of the SDFT within the DFTS in dressage horses have been rather disappointing. Although lameness has often improved, minor career-limiting gait abnormalities have persisted.

RUPTURE OF THE SUPERFICIAL DIGITAL FLEXOR TENDON IN PLEASURE HORSES

SDF tendonitis is an uncommon injury in general-purpose riding horses, but spontaneous rupture occurs occasionally in old horses in the midmetacarpal region.⁸ This results in acute-onset, severe lameness often identified in horses turned out in a field. There is diffuse soft tissue swelling in the metacarpal region, and hyperextension of the fetlock if the horse will bear weight on the limb. If the limb is picked up, a palpable defect can be identified in the SDFT, with the tendon flaccid both proximal and distal to the site of rupture. Ultrasonographic examination reveals complete loss of fiber pattern and an anechogenic region at the site of rupture. Treatment consists of application of a Robert Jones bandage, NSAIDs, and box rest for at least 2 months, with a progressive increase in walking exercise thereafter. Nine of nine horses aged 18 to 22 years made a complete functional recovery, returning to light work within 6 months of injury.⁸ One horse subsequently ruptured the contralateral SDFT.

Rupture of the SDFT at the musculotendinous junction is discussed in Chapter 75.

Chapter 70

The Deep Digital Flexor Tendon

Sue J. Dyson

ANATOMY

In the forelimb the deep digital flexor tendon (DDFT) has three heads: the humeral head, the largest, and the smaller radial and ulnar heads.¹ The tendon of the humeral head

develops 8 to 10 cm proximal to the antebrachiocarpal joint, but muscular tissue persists to the level of the antebrachiocarpal joint, where the ulnar and radial heads join. The merged tendon is triangular in cross-section within the carpal canal but becomes more rounded in the metacarpal region. The accessory ligament of the DDFT (ALDDFT) merges with the DDFT in the middle third of the metacarpal region.

In the hindlimb the DDFT is formed by a large lateral digital flexor tendon and a smaller medial digital flexor tendon. The lateral digital flexor tendon incorporates the caudal tibialis tendon and passes over the sustentaculum tali within the tarsal sheath. The medial digital flexor tendon passes over the proximal tubercle of the talus, on the medial aspect of the talus, in its own synovial sheath. These two tendons fuse in the proximal metatarsal region.

In the proximal metatarsal region the DDFT is a large oval structure that becomes smaller farther distally. The ALDDFT in the hindlimb varies in size and is generally comparatively smaller than in the forelimb and may be absent; in some horses it is a bifid structure.

At the fetlock region the DDFT becomes wider, elliptical, and fibrocartilaginous and is enclosed within the digital flexor tendon sheath (DFTS). In the pastern region the tendon becomes bilobed. At the level of the proximal part of the middle phalanx the dorsal part of the tendon becomes a fibrocartilaginous pad. Distally the DDFT is molded to the palmar or plantar aspect of the navicular bone. The DDFT is broad, has a terminal fanlike expansion containing cartilage, and inserts on the facies flexoria of the distal phalanx, delineated dorsally by the semilunar line and the adjacent surface of the cartilage of the foot.

The DDFT has a high modulus of elasticity (1585 MPa) and a considerable strength to rupture (approximately 1700 daN).¹ The ALDDFT has a low modulus of elasticity (490 MPa) and a moderate strength to rupture (approximately 490 daN). The DDFT limits carpal and fetlock extension under high loads. In the fetlock region the DDFT is under tension and compression. It is therefore fibrocartilaginous in this region and in the pastern, where the tendon is under pressure from the tuberositas flexoria, a transverse prominence on the proximal palmar aspect of the middle phalanx. In the digit the DDFT facilitates flexion of the proximal interphalangeal joint during weight bearing and stabilizes the distal interphalangeal joint.

The position of the DDFT and the navicular bone varies considerably during the stance phase. In the full weight-bearing position the DDFT is in close contact with only the distal border of the navicular bone, but during propulsion it comes into full contact with the palmar aspect of the bone. The tendon is stretched maximally as active contraction of the muscle bellies and the elasticity in the tendon result in elevation of the fetlock and extension of the distal interphalangeal joint. During the swing phase of the stride the DDFT relaxes. The DFTS facilitates displacement of the digital flexor tendons during flexion and extension.

DDFT injuries occur most commonly in the fetlock or pastern regions within the DFTS or within the hoof capsule. Injuries in the metacarpal or metatarsal regions and the carpus or tarsus are less common.²⁻²²

DEEP DIGITAL FLEXOR TENDONITIS ASSOCIATED WITH RECURRENT DESMITIS OF THE ACCESSORY LIGAMENT OF THE DEEP DIGITAL FLEXOR TENDON

Injuries of the DDFT in the carpal or metacarpal region, proximal to the DFTS, are rare except in association with chronic desmitis of the ALDDFT (see Chapter 71). Recurrent desmitis may be accompanied by pathological lesions of the DDFT.² Because of the close proximity of the DDFT and its accessory ligament, it is difficult to assess each structure accurately by palpation, especially with chronic enlargement of the ALDDFT, which may wrap around the borders of the DDFT. Ultrasonographic examination may reveal slight enlargement of the DDFT. The dorsal

border may be less well defined, and diffuse hypoechogenic regions may occur within the DDFT, extending a variable distance proximodistally. These injuries usually result in recurrent lameness.

It has also been noted that in association with substantial enlargement of the superficial digital flexor tendon (SDFT) because of chronic tendonitis, the DDFT becomes smaller in cross-sectional area.³ With chronic enlargement of the ALDDFT, the DDFT also may reduce in size.

Primary deep digital flexor tendonitis in the proximal metacarpal region is rare. A single case was recorded by Genovese and Rantanen⁴ in an 8-year-old Quarter Horse used for English pleasure riding. Lesions have been identified using magnetic resonance imaging in a small number of horses.^{5,6} Occasionally, traumatic injuries of the DDFT have been seen within the carpal sheath (see Chapter 75).

DEEP DIGITAL FLEXOR TENDONITIS IN THE CARPAL SHEATH SECONDARY TO SOLITARY OSTEOCHONDROMA OR A DISTAL RADIAL PHYSEAL EXOSTOSIS

Lesions of the DDFT within the carpal sheath are an unusual cause of lameness except secondary to irritation by a solitary osteochondroma or a distal radial physeal exostosis.⁷ An osteochondroma is an exostosis continuous with the cortex of the bone and is covered by cartilage. The osteochondroma develops immediately proximal to the distal radial physis, often medial to the midline. Lameness is sudden in onset and usually is accentuated by carpal flexion. There is usually distention of the carpal sheath, but some horses with physeal exostoses have severe, sporadic lameness with no localizing clinical signs. An osteochondroma is readily identifiable radiologically, but some physeal exostoses are more readily identified using ultrasonography. Ultrasonographic examination from the distal medial aspect of the antebrachium also reveals the abnormal bone contour, an abnormal amount of fluid within the carpal sheath, and an irregular dorsal contour of the DDFT. Treatment is by tenoscopic surgical removal of the osteochondroma or exostosis and debridement of any torn fibers of the DDFT. The prognosis for return to athletic function is excellent.

DEEP DIGITAL FLEXOR TENDONITIS WITHIN THE DIGITAL FLEXOR TENDON SHEATH IN THE FETLOCK REGION

Some enlargement of the DFTS is common in hindlimbs, often unassociated with lameness, but occurs less frequently in forelimbs. Sudden-onset lameness associated with distention of a DFTS in a forelimb or a hindlimb may be caused by a variety of different lesions, but deep digital flexor tendonitis always should be considered^{5,6} (see Chapter 74). It is rare to identify lesions of the DDFT within a DFTS that is not distended. Some horses develop deep digital flexor tendonitis *after* long-term chronic enlargement of the DFTS.

Lameness associated with DDFT lesions within the DFTS occurs more frequently in hindlimbs than in forelimbs and in horses from a variety of disciplines. The

Fig. 70-1 • Transverse (**A**) and longitudinal (**B**) ultrasonographic images of the left hindlimb of a horse with sporadic left hindlimb lameness. There was chronic moderate distention of the digital flexor tendon sheath of both hindlimbs. There is diffuse reduction in echogenicity in the dorsal half of the deep digital flexor tendon (**A**, arrows) and loss of fiber pattern (**B**, arrows).

condition usually occurs unilaterally, although it has been seen bilaterally in the hindlimbs of several Warmblood dressage horses³ and in show jumpers.

Lameness varies from mild to moderately severe. Distention and thickening of the DFTS may make accurate palpation of the DDFT difficult. In some horses pain can be elicited by palpation of the margins of the tendon or by firm pressure applied to its palmar (plantar) aspect. The tendon should be assessed throughout its length, proximal and distal to the fetlock. In the acute stage there may be localized heat. Passive flexion of the lower limb may induce pain. If forelimb lameness is only mild in straight lines, it may be exaggerated on the lunge on a soft surface, especially in medium and extended trot. Distal limb flexion often accentuates the lameness. Occasionally in hindlimbs lesions of the DDFT within the DFTS have been the cause of sporadic lameness. The intermittent nature of the lameness makes definitive identification of the cause a diagnostic challenge. Such a history seen in conjunction with distention of the DFTS should prompt ultrasonographic examination (Figure 70-1).¹⁶

Intrathecal analgesia of the DFTS usually results in substantial improvement but rarely alleviates lameness. Better improvement is seen after perineural analgesia of the palmar or plantar nerves and palmar metacarpal (plantar metatarsal) nerves (a so-called low 4-point block) proximal to the distended DFTS. In horses in which the metacarpophalangeal (metatarsophalangeal) joint capsule also is distended, performing intraarticular analgesia may be necessary to be sure that distention is not contributing to pain.

Definitive diagnosis requires ultrasonographic examination. Four types of lesions involving the DDFT have been identified: enlargement and change in shape of the tendon, focal hypoechoic lesions within the tendon or on its border, mineralization within the DDFT, and marginal tears.⁸⁻¹⁴ The first three are readily diagnosed using

diagnostic ultrasonography, but the marginal tears are much more difficult to identify. Surgical exploration may be required for definitive diagnosis.⁸ Acute-onset focal hypoechoic areas generally are not seen with preexisting adhesion formation, although any of the other lesions may be.

The normal DDFT changes in its shape and cross-sectional area from proximally to distally, but it is usually bilaterally symmetrical. A normal DDFT is uniform in its echogenicity, and its margins are clearly defined. At the site at which the ALDDFT merges with the DDFT there may be a relatively hypoechoic region, especially in the hindlimbs. This is a normal variant. Hypoechoic artifacts are induced readily in the distal fetlock and pastern regions if the ultrasound transducer is not perpendicular to the tendon, and in these regions evaluating the SDFT and DDFT simultaneously is difficult. Echogenic synovial plicae (mesotendon) extend medially and laterally from the DDFT to the DFTS wall in the proximal recess of the DFTS (Figure 70-2, A). These are seen much more obviously when the tendon sheath is distended and should not be mistaken for marginal tears or adhesions. With chronic tenosynovitis, these plicae may become thickened. Distal to the fetlock is an echogenic palmar (plantar) synovial fold that should not be confused with an adhesion (see Figure 70-2, B). The ergot on the palmar (plantar) distal aspect of the fetlock prohibits ultrasonographic evaluation at this level, and lesions of the DDFT may be missed. The size of the palmar (plantar) annular ligament (PAL) and the presence of subcutaneous fibrosis should also be evaluated because this may influence prognosis.¹³

Enlargement or Change in Shape of the Deep Digital Flexor Tendon

In horses with low-grade injuries the only detectable ultrasonographic abnormality is a change in shape or size of the

Fig. 70-2 • Transverse ultrasonographic images of the digital flexor tendon sheath (DFTS) in **(A)** the distal metacarpal region and **(B)** the pastern. Medial is to the left. **A**, An abnormal amount of fluid is within the DFTS, but the deep digital flexor tendon (DDFT) appears normal. Note the prominent synovial plica extending from the lateral aspect of the DDFT. This plica also is thickened slightly, and other echogenic material is within the anechogenic synovial fluid, but the horse had no associated lameness. **B**, Note the abnormal amount of fluid within the DFTS, and the synovial plica on the palmar aspect of the DDFT. These are normal anatomical structures that are visible most readily when the DFTS is distended.

DDFT. The echogenicity and fiber pattern may appear normal; therefore these injuries are easily overlooked. The DDFT may look rounder in cross-section, rather than elliptical. Careful comparison with the contralateral limb at the same distance distal to the accessory carpal bone is important for accurate diagnosis. Comparison of the relative sizes of the SDFT and DDFT can also be helpful. Cross-sectional area measurements of the SDFT are prone to error at this level, and therefore measurements of the dorsopalmar thickness of the SDFT and DDFT are more accurate. If the horse fails to respond satisfactorily to conservative management, then consideration should be given to the presence of a marginal tear that may not be detectable with ultrasonography.³

Constriction of the DFTS and its contents by an enlarged PAL may result in secondary compression of the DDFT.

Focal Hypoechoic Lesions

The cross-sectional area of the DDFT may be enlarged. Focal hypoechoic lesions vary in size and position within the cross-section of the tendon and in length. Some are small, occupying less than one tenth of the cross-sectional area of the tendon and extending less than 1 cm proximodistally, whereas others are considerably more extensive (Figure 70-3).⁵ Generally, larger lesions are associated with more severe lameness. These lesions generally occur immediately proximal to, or at the level of, the fetlock joint. An abnormal amount of synovial fluid is found within the DFTS, and sometimes adhesions are identified.

In some horses, inspection of the medial or lateral border of the DDFT reveals loss of definition of the margin

of the tendon and an area of reduced echogenicity, indicating major fiber disruption. These lesions are easy to diagnose. The marginal tears described subsequently (see page 730) are more difficult to detect.

Small lesions have resolved with rest, and horses have returned to full athletic function. However, large lesions tend to persist, and ultrasonographic examination may reveal no change, even if the horse has been rested for more than 1 year. Large lesions have been associated with recurrent lameness.⁸ Intrathecal medication with hyaluronan, triamcinolone acetonide, or methylprednisolone acetate has resulted in only temporary relief. Desmotomy of the PAL has resulted in only temporary remission of clinical signs. The prognosis for return to full athletic function is guarded. A few sports horses have been successfully managed by intralesional injection of cultured mesenchymal stem cells, with subsequent ultrasonographic resolution of lesions and return to full athletic function, without recurrent injury for up to 3 years after treatment.²³

Fibrosis and Mineralization within the Deep Digital Flexor Tendon

Some horses develop widespread hyperechogenic foci within the DDFT in the fetlock region. Some of these create shadowing artifacts and therefore represent mineralization (Figure 70-4). The foci generally but not invariably reflect a chronic injury.¹⁴ If extensive, they make evaluation of the remaining tendon architecture difficult because of acoustic shadowing. The cross-sectional area of the tendon usually is enlarged. Ill-defined hypoechoic regions

Fig. 70-3 • Transverse ultrasonographic images of the distal metatarsal region of a horse with acute-onset right hindlimb lameness associated with distention of the digital flexor tendon sheath (DFTS). Medial is to the left. An abnormal amount of fluid is within the DFTS. **A**, There is a well-defined anechogenic lesion within the deep digital flexor tendon, close to the plantar border. Note also the rather poorly defined dorsal border. **B**, Slightly farther distally the lesion can be seen to involve the dorsal and plantar borders of the tendon.

Fig. 70-4 • Transverse ultrasonographic image of the distal metatarsal region of an 8-year-old event horse with chronic right hindlimb lameness associated with distention of the digital flexor tendon sheath. Medial is to the left. The deep digital flexor tendon (DDFT) is enlarged. Many hyperechogenic foci are within the DDFT, resulting in shadowing artifacts that make accurate evaluation of the structure of the more dorsal aspects of the tendon impossible.

often extend proximally or distally from hyperechogenic foci or are remote from them. Fibrous adhesions may extend from the DDFT to the DFTS wall.

The cause of these hyperechogenic lesions is unknown, although some affected horses have a history of previous

injections of corticosteroids into the DFTS. Most of the affected horses are middle-aged Warmblood-type horses used for show jumping or dressage. These lesions tend to result in persistent long-term lameness.

Marginal Tears of the Deep Digital Flexor Tendon

Marginal tears of the DDFT have been identified on the medial, lateral, and dorsal borders.^{3,8} Lesions involving the lateral margin have been identified most commonly, varying in length (Figure 70-5). Frequently the proximal extent of the tear is at the level of the manica flexoria. Some lesions extend as far distally as the proximal digital annular ligament. In some horses the lesion is a frontal (dorsal) plane split in the margin of the tendon; in other horses a sagittal tear of fibers occurs. Frontal plane splits in the DDFT, which may be the result of compression of the tendon with the fetlock in extension, may not be detectable by ultrasonography, although often a detectable enlargement of the cross-sectional area of the DDFT exists. The affected margin may be slightly less well defined compared with normal findings. Occasionally a torn echogenic strand is seen partially detached from the DDFT. Care must be taken not to confuse the synovial plicae on the medial and lateral borders of the tendon with a marginal tear. It is important to recognize that lesions may occur at more than one location; therefore evaluation of all accessible regions of the DDFT is recommended.

Diagnosis is based on surgical exploration of the DFTS, which is indicated if a horse has pain associated with the DFTS along with abnormalities of the DDFT detected by ultrasonography, or no detectable changes, but a failure to

Fig. 70-5 • The lateral margin of the deep digital flexor tendon (DDFT) within the digital flexor tendon sheath in the distal metacarpal region, viewed tenoscopically. The DDFT has a marginal tear. Ultrasonographic examination revealed slight enlargement of the DDFT, but otherwise the tendon appeared structurally normal. (Courtesy I.M. Wright, Newmarket, England.)

respond to conservative management (see Chapter 74). Tenoscopic evaluation via a portal on the proximopalmar (proximoplantar) aspect of the pastern enables the most comprehensive view of the flexor tendons.¹⁷ However, proper evaluation of the DDFT underneath the manica flexoria may not be possible unless the manica flexoria is transected. Treatment can be by debridement of the lesion, which can be done tenoscopically, or by debridement and suturing. The latter may be achieved most effectively by transection of the palmar PAL and opening of the DFTS, followed by primary closure of the PAL; however, this technique is potentially associated with some morbidity. Some horses develop thickening of the PAL and/or the proximal digital annular ligament postoperatively, together with subcutaneous fibrosis, which results in persistent lameness. Five of six horses used for dressage, show jumping, or horse trials treated by open surgery to repair defects in the margin of the DDFT had persistent lameness associated with this type of reaction.³ Therefore tenoscopic debridement is the preferred method of management, although the prognosis remains guarded. Prognosis for horses treated by tenoscopic debridement depends in part on the length of the lesion, with 40% to 59% of horses returning to full athletic function.^{10,12} Generally horses with hindlimb injuries have had a better prognosis than those with forelimb injuries.

DEEP DIGITAL FLEXOR INJURIES IN THE PASTER REGION

The DDFT within the pastern remains within the DFTS, over which lie the thin proximal and distal digital annular ligaments. The tendon is therefore relatively close to the

skin surface and so is vulnerable to the effects of direct trauma and puncture wounds.

In the pastern region the DDFT is a bilobed structure, each lobe being similar in size and shape at any level. Care must be taken when evaluating the tendon by ultrasonography because off-incidence artifacts are created readily. These may be seen as central, round hypoechogenic areas and should not be mistaken for lesions.

Deep Digital Flexor Tendonitis

Deep digital flexor tendonitis restricted to the pastern region is not a common cause of lameness and occurs less often than sprain of the oblique sesamoidean ligaments or strain of one of the branches of the SDFT (see Chapter 32). Many horses with lesions of the DDFT have lesions that extend into the hoof capsule and are discussed in Chapter 32. Tendonitis of the DDFT in the pastern region is seen most often in skeletally mature horses and occurs more often in forelimbs than in hindlimbs. Deep digital flexor tendonitis occurs in a variety of sports horses, but the incidence in racehorses is lower than in other performance horses.

Deep digital flexor tendonitis in the pastern region usually results in acute-onset, unilateral, moderate-to-severe lameness that is persistent. Less commonly lameness is detectable only after maximal exertion and has resolved with rest but has progressively worsened over 1 to 2 years.³ Slight, firm soft tissue swelling may occur on the palmar midline of the pastern region. Often, slight distention of the DFTS occurs in the pastern region, but an obvious windgall may not be apparent. Firm palpation on, or just to one side of, the palmar midline of the pastern region may cause pain. Lameness is often worse on a soft surface compared with a hard surface and generally is improved substantially by perineural analgesia of the palmar nerves at the level of the proximal sesamoid bones.

Diagnosis is based on ultrasonographic evaluation. Careful comparison of the size and shape of the contralateral DDFT is useful. The ease with which the tendon can be evaluated distally in the pastern depends on the conformation of the pastern and foot. Evaluation is more difficult in horses with a narrow heel and a deep cleft between each bulb. A lesion may involve just one lobe of the tendon or both and is usually characterized by enlargement and alteration in shape of the tendon, with or without hypoechogenic regions within the tendon. Off-incidence imaging may be necessary to identify areas of fibrosis. The medial and lateral margins of the tendon should be carefully evaluated. In horses with chronic injuries focal hyperechogenic foci consistent with dystrophic mineralization may be seen. Occasionally a complex of injuries is identified involving not only the DDFT, but also a distal sesamoidean ligament or the distal digital annular ligament. All structures should be examined carefully and systematically. Horses with lesions restricted to the DDFT that have been recognized early usually respond reasonably to prolonged rest (6 to 12 months), with progressive resolution of hypoechoic defects as assessed by ultrasonography. Some enlargement of the tendon may persist long term. Horses with more chronic injuries or complex injuries including adhesion formation respond less favorably, with a high incidence of recurrent lameness, even with surgical intervention. There are anecdotal reports of successful

treatment by intralesional injection of platelet-rich plasma or cultured mesenchymal stem cells. However, if the periphery of the DDFT is not intact, leakage of mesenchymal stem cells may result in echogenic tissue being laid down within the DFTS, with associated chronic lameness.

Lesions of the DDFT have been described in association with primary injuries of the distal digital annular ligament diagnosed using magnetic resonance imaging.²⁴ Such injuries have been characterized by focal thickening of the distal digital annular ligament and increased signal intensity in at least T1- and T2-weighted images. It was suggested that lameness could be successfully treated by transection of the distal digital annular ligament, but given the integral relationship between the DDFT and the distal digital annular ligament it is difficult to see how this can be achieved. In my clinical experience injuries of the DDFT and the ipsilateral aspect of the distal digital annular ligament are usually identified in association with other soft tissue injuries on the ipsilateral aspect of the foot.

Injury Caused by Blunt Trauma in the Pastern Region

Direct blunt trauma caused by, for example, a severe overreach can result in severe inflammation of the subcutaneous tissue, the digital annular ligaments, and sometimes also the DDFT. If the proximal or distal digital annular ligament becomes thickened and fibrosed, this can create undue pressure on the DDFT and chronic pain, without any structural abnormality of the DDFT. In the acute stage, generalized swelling occurs in the pastern region, and palpation elicits pain. Ultrasonographic examination is required to determine which structures have been damaged. This may need to be repeated as fibrotic reactions develop in the ensuing weeks. The prognosis is generally favorable unless the digital annular ligaments become substantially thickened or the palmar aspect of the DDFT is torn.

An overreach sometimes results in laceration of the skin and the palmar aspect of the DDFT. These lacerations may not coincide because of the mobile nature of the skin, and damage to the DDFT may be overlooked unless the tendon is examined by ultrasonography. One or both branches of the SDFT may also be damaged, so all structures should be evaluated carefully and systematically. Such lesions often heal with extensive fibrotic reactions and adhesion formation to the DFTS, which may result in chronic lameness.

Puncture Wounds of the Deep Digital Flexor Tendon and Blunt Trauma

Puncture wounds in the palmar (plantar) aspect of the pastern region, caused by sharp objects such as a flint, can cause sudden-onset, moderate-to-severe lameness and rapid development of effusion within the DFTS. Ultrasonographic examination can be used to determine whether the DDFT was penetrated. An anechoic defect may be seen in its palmar border. With prompt treatment by vigorous lavage of the DFTS combined with systemic broad-spectrum antimicrobial therapy, the outcome may be favorable. Ideally the DFTS and its contents should be inspected using an arthroscope to determine if any foreign material

was embedded within the DDFT that might seriously compromise the outcome.

Alternatively, blunt trauma to the pastern region may result in an innocuous wound followed by the subsequent development of severe lameness in association with a core lesion of the DDFT. It is postulated that this may be the result of avascular necrosis of the tendon.¹⁸ The prognosis is poor.

Rupture of the Deep Digital Flexor Tendon

Rupture of the DDFT in the pastern region or within the hoof capsule is usually a sequela to a previous neurectomy of the palmar digital nerves. Neurectomy is usually performed because of suspected navicular disease or to relieve chronic foot pain of unknown cause. Preexisting lesions of the DDFT are likely to predispose to tendon rupture. I have never examined a horse with spontaneous rupture of the DDFT that did not have a history of neurectomy. Lameness may be insidious and progressive or sudden in onset, associated with extensive swelling in the pastern region. Thickening results from enlargement of the DDFT, peritendinous fibrosis, and, in horses with long-term injuries, secondary superficial digital flexor tendonitis. Complete rupture results in the toe of the limb flipping up when the limb is bearing weight (Figure 70-6). These clinical signs are pathognomonic. In such horses the proximal end of the DDFT may retract proximally, resulting in the SDFT becoming opposed to the fibrocartilaginous scutum on the palmar aspect of the pastern region. Radiologically a variable degree of subluxation of the distal interphalangeal joint exists, depending on the degree of integrity of the DDFT. The prognosis is hopeless for athletic function. Extensive peritendinous fibrosis ultimately develops, providing adequate

Fig. 70-6 • The distal aspect of the right forelimb of a horse with rupture of the deep digital flexor tendon 5 months after palmar digital neurectomy. The toe is flipped upward, associated with subluxation of the distal interphalangeal joint. There is considerable thickening in the pastern region caused by peritendinous fibrosis. Note the surgical scar.

support to preserve life for breeding, assuming that the contralateral limb can withstand the strain in the interim. Arthrodesis of the distal interphalangeal joint remains a management option for salvage of a horse for breeding purposes or pasture soundness.

LESIONS OF THE DEEP DIGITAL FLEXOR TENDON WITHIN THE HOOF CAPSULE

Lesions of the DDFT within the hoof capsule are discussed in Chapter 32.

LESIONS OF THE DEEP DIGITAL FLEXOR TENDON IN THE TARSAL AND PROXIMAL METATARSAL REGIONS

Primary deep digital flexor tendonitis in the tarsal or proximal metatarsal regions is an unusual cause of hindlimb lameness (see Chapter 76). Lesions in the proximal metatarsal region have been identified in young Thoroughbreds in race training, with lameness associated with mild swelling in the proximal plantar metatarsal region. Lameness was improved transiently by intraarticular analgesia of the tarsometatarsal joint in two horses, presumably because of local diffusion of local anesthetic solution.³ Subtarsal analgesia of the plantar and plantar metatarsal nerves alleviated lameness in one horse. Ultrasonographic examination revealed enlargement of the DDFT in the proximal metatarsal region, poor definition of the margins, and diffuse hypoechogenic areas within the tendon. Rest for 3 months resulted in resolution of lameness, and the prognosis is favorable for return to racing.

Primary lesions of the DDFT in the tarsal region have been identified only in skeletally mature horses and are comparatively rare. Lameness is sudden in onset and moderate in degree. Mild distention of the tarsal sheath may occur, but localizing signs may be absent. Lameness is improved by perineural analgesia of the tibial and fibular nerves, but it is unaffected by intraarticular analgesia of the hock joints. Diagnosis relies on ultrasonographic examination. The DDFT may be examined from the plantaromedial aspect of the hock within the tarsal sheath. The DDFT is a large oval structure with well-defined margins. The dorso-lateral aspect of the tendon may appear slightly less echogenic than the remainder of the tendon due to structural adaptation, and care should be taken not to misinterpret this as a lesion (Figure 70-7). Careful comparison with the contralateral limb is essential. Abnormalities include enlargement of the tendon, poor demarcation of the borders, and hypoechogenic areas. Lesions may also be identified by tenoscopic examination of the tarsal sheath (see Chapters 24 and 76).

Lesions of the DDFT also have been identified in association with bony lesions of the sustentaculum tali of the

Fig. 70-7 • Transverse ultrasonographic image of the plantaromedial aspect of the distal tarsal region of a normal horse. Medial is to the left. Note the relatively hypoechogenic area dorsolaterally (arrows), a normal finding.

fibular tarsal bone (calcaneus) and ectopic mineralization within the tarsal sheath.¹⁹ These horses may have fibrillation of the DDFT and adhesion formation. These lesions generally are seen with obvious distention of the tarsal sheath and long-term lameness and probably occur secondary to primary pathological conditions of the bone. The sustentaculum tali should be evaluated radiologically using plantarolateral-dorsomedial oblique and flexed dorsoplantar images. The prognosis for athletic performance is poor with conservative or surgical management.

Dorsomedial luxation of the DDFT secondary to congenital malformation of the sustentaculum tali has been recognized in young Saddlebred horses and occasionally in Thoroughbreds.^{3,20} Clinically the plantar aspect of the tarsal region appears broader than normal, with tarsus valgus. Lameness may not be obvious. Diagnosis is based on radiological examination: the sustentaculum tali appears flattened in a dorsoplantar (flexed) image.²¹ This may result in a mechanical lameness. Surgical treatment has been attempted, but the horse did not race.²² Congenital medial displacement of both the DDFT and SDFT in a hindlimb has also been seen, with a secondary valgus deformation of the metatarsal region and distal physeal trauma of the third metatarsal bone.²³

INFECTION OF THE DEEP DIGITAL FLEXOR TENDON

Infection of the DDFT is discussed in Chapter 37 (see page 423).

Chapter 71

Injuries of the Accessory Ligament of the Deep Digital Flexor Tendon

Sue J. Dyson

ANATOMY

In the forelimbs the accessory ligament of the deep digital flexor tendon (ALDDFT) is a substantial structure, similar in size to the deep digital flexor tendon (DDFT). The ALDDFT continues the common palmar ligament of the carpus, originating principally from the palmar aspect of the third carpal bone.¹ Proximally the ALDDFT is broad and rectangular in cross-section; farther distally it becomes narrower and thicker and blends with the DDFT in the middle one third of the metacarpal region. Fibrous bundles run from the lateral border of the ALDDFT to the superficial digital flexor tendon (SDFT) in the proximal half of the metacarpal region, and these predispose the horse to develop adhesions between the ALDDFT and the SDFT in horses with severe superficial digital flexor tendonitis or severe desmitis of the ALDDFT. The ALDDFT forms the dorsal wall of the carpal canal, within which is the carpal synovial sheath, which is interspersed between the DDFT and its accessory ligament.

In the hindlimbs the size of the ALDDFT varies extremely, but it is generally smaller than in the forelimb and rarely more than half the thickness of the DDFT. The ligament is usually symmetrical in the left and right hindlimbs of an individual horse. A recent postmortem study showed that the ALDDFT was absent in 6% of 165 hindlimbs and was occasionally a bifid structure.²

A forelimb ALDDFT has a low modulus of elasticity and a moderate strength to rupture, whereas the DDFT has a high modulus of elasticity and a strength to rupture that is more than three times that of the forelimb ALDDFT. In the forelimb the ALDDFT is loaded during the late stance phase, during extension of the digital joints,¹ or when landing over a fence.³ The ALDDFT prevents overstretching of the DDFT by passively carrying the load during maximal extension of the distal interphalangeal and metacarpophalangeal joints. The ALDDFT also functions to facilitate carpal extension when the limb is loaded.¹ During flexion of the limb the ALDDFT is relaxed completely, and active muscle contraction results in the DDFT sliding proximally within the carpal sheath. The role of the ALDDFT in the hindlimb is less clear.

Desmitis of the ALDDFT usually occurs in forelimbs⁴⁻⁹ but *occasionally* is recognized as a cause of hindlimb lameness.^{4,10-13} In forelimbs desmitis may occur alone^{4,7} as an acute injury or may develop secondarily to previous severe tendonitis of the SDFT. In the latter case the SDFT is

enlarged substantially and wraps around the medial and lateral margins of the DDFT. Adhesions develop between adjacent structures. In horses with chronic, severe desmitis of the ALDDFT, additional injury may occur to the adjacent DDFT.^{7,8} A flexural deformity of the metacarpophalangeal or metatarsophalangeal joint may develop after severe injury to the ALDDFT.^{4,9} Occasionally a flexural deformity of the metatarsophalangeal joint develops in one or both hindlimbs without a history of lameness, but ultrasonography reveals chronic architectural changes in the ALDDFT.¹¹⁻¹³ The flexural deformity may be relieved by desmotomy of the ALDDFT, provided that contracture of periarticular soft tissues has not already occurred.

PATHOGENESIS

Degenerative aging changes take place in the ALDDFT of forelimbs, and these may be a substantial predisposing factor in the development of desmitis. The amount of fibrillar collagen and number of large collagen fibers in the ALDDFT decrease with increasing age.¹⁴ In a study of mechanical properties of the ALDDFT in relationship to age, failure forces of the ALDDFT of older horses were significantly lower than those of the ALDDFT in younger horses.¹⁵ Fibrillar ruptures developed in the ALDDFT of old horses at forces and strains that were approximately half those of the forces inducing total failure in young horses. It has been suggested that fibrillar rupture occurs at relatively low strains in older horses and that repetitive micro-trauma may lead to clinical desmitis.^{14,15}

The incidence of desmitis of the ALDDFT is rather different from that of other tendonous and ligamentous injuries. Injuries occur more often in horses older than 8 years of age.⁴⁻⁶ The incidence in Thoroughbreds is comparatively low (rare in the Standardbred), and therefore this is an unusual injury in event horses or racehorses, except in older steeplechasers. Desmitis is a relatively common injury in ponies (see Chapter 126) and crossbred horses, including pleasure horses.^{4,5} The incidence in Warmblood horses is also high.⁶ Desmitis occurs in older show jumpers (see Chapter 115), especially Grand Prix-level horses,¹² in older dressage horses,¹² and also sometimes in young, extravagantly moving dressage horses (see Chapter 116). Desmitis is generally a unilateral forelimb injury (Figure 71-1), although occasionally it occurs bilaterally, and is a rare cause of hindlimb lameness.

In hindlimbs, desmopathy of the ALDDFT has been seen most frequently in cob-type breeds¹¹⁻¹³ and Quarter Horses or Quarter Horse crosses,¹⁶ even in some horses or ponies of a comparatively young age, and does not appear to have been induced traumatically in all horses. In some of these horses the condition has been bilateral, developing simultaneously or sequentially in each hindlimb. Desmopathy frequently has been associated with a tendency to stand with the fetlock of the affected limb partially flexed (Figure 71-2), resulting in the development of a flexural deformity. The condition also has been recognized together with swelling on the plantar aspect of the pastern, associated with concurrent desmitis of the straight or oblique sesamoidean ligaments.¹¹

Fig. 71-1 • **A**, Transverse ultrasonographic image of the palmar metacarpal soft tissue structures, 11 cm distal to the accessory carpal bone, of an 8-year-old Grand Prix show jumper. Medial is to the left. The accessory ligament of the deep digital flexor tendon (ALDDFT) is considerably enlarged (*arrows*) and diffusely hypoechoic, with focal anechoic areas dorsomedially. **B**, Longitudinal ultrasonographic image of the palmar metacarpal soft tissues in zone 2A of the same horse as in **A**. Proximal is to the left. There is a diffuse reduction in echogenicity of the ALDDFT and poor fiber pattern.

HISTORY AND CLINICAL SIGNS

There is usually an acute-onset moderate-to-severe lameness during exercise.⁴⁻⁶ A show jumper may pull up lame after jumping a large fence or after a water jump.¹² Swelling develops rapidly in the proximal one third of the metacarpal region, dorsal to the SDFT. Determining by palpation whether the DDFT or accessory ligament is enlarged can be difficult, but injuries of the DDFT in this area are unusual. Some horses develop desmitis secondary to previous superficial digital flexor tendonitis, and in these horses separating the margins of the SDFT from the ALDDFT often is difficult.

Clinical signs include swelling, heat, pain on palpation, and lameness. The horse may stand with slight elevation of the heel and flexion of the metacarpophalangeal joint. Some degree of swelling often persists, even after long-term convalescence. In horses with reinjury, new swelling may be only slight, and careful palpation is required to identify a focus of pain. Occasionally there are no localizing clinical signs, but lameness is improved by palmar and palmar metacarpal (subcarpal) nerve blocks or abolished by median and ulnar nerve blocks. Lesions of the ALDDFT that were not detectable ultrasonographically have been identified with magnetic resonance imaging.^{17,18} However, great care must be taken in interpretation because in normal horses the ALDDFT may have higher signal intensity than the DDFT or the SDFT in some image sequences.^{19,20} There also may be bands of lower and higher signal intensity reflecting histological variation in infrastructure. Focal lesions have also been identified ultrasonographically at the origin of the ALDDFT on the palmar aspect of the third carpal bone.¹⁸

Some horses with desmitis in a hindlimb have acute-onset lameness associated with localized swelling. In sports horses injury may be localized to the proximal metatarsal region, resulting in subtle edematous swelling in the proximomedial aspect, whereas in general-purpose riding horses injury is usually further distal in the metatarsal region, with more obvious enlargement of the ALDDFT. However, some horses do not have an acute-onset lameness but have an insidious onset of stiffness and a tendency to stand with the fetlock semiflexed, progressing to inability to load the heel of the affected limb. This may be unilateral or bilateral.¹¹ Teenage cob-types and British native pony breeds appear particularly at risk. Careful palpation may reveal enlargement of the ALDDFT, but the thick skin of these types of horse may prohibit accurate palpation.

ULTRASONOGRAPHY

Diagnosis is usually confirmed by ultrasonography (see [Figures 71-1 to 71-3](#)). The transducer should be focused initially at the depth of the ALDDFT, which should be examined in transverse and longitudinal planes. Comparative images of the contralateral limb also should be obtained. If the transducer has a built-in standoff, this may create artifacts at the level of the ALDDFT. Some lesions are localized to the lateral or, less commonly, the medial margin of the ALDDFT, and these lesions may be missed unless the limb is evaluated from the lateral and medial aspects respectively, preferably using a standoff pad.

The ALDDFT is normally the most echogenic of the palmar metacarpal (plantar metatarsal) soft tissue structures, and its borders are well defined. In some ponies the

Fig. 71-2 • A, A 6-year-old Fell pony with a flexural deformity of the left hind fetlock associated with chronic desmopathy of the accessory ligament of the deep digital flexor tendon (ALDDFT). The pony was unable to place the heel of the left hind foot on the ground. Even when the pony was heavily sedated, extending the left hind fetlock was not possible. Firm enlargement on the plantar aspect of the pastern associated with desmitis of the straight distal sesamoidean ligament was also apparent. Similar abnormalities had developed in the right hindlimb approximately 12 months previously. **B**, Transverse ultrasonographic image of the plantar metatarsal soft tissues approximately 10 cm distal to the tarsometatarsal joint. Medial is to the left. The ALDDFT is enlarged considerably (*arrows*), and there is a large anechogenic lesion centrally. **C**, Longitudinal ultrasonographic image in zone 2A. Proximal is to the left. There is marked loss of fiber pattern in the ALDDFT (*arrows*).

Fig. 71-3 • A, Transverse ultrasonographic image of the left hindlimb of a 12-year-old Thoroughbred-cross event horse with acute-onset right hindlimb lameness. Medial is to the left. The image was acquired from the plantaro-medial aspect of the limb at 5 cm distal to the tarsometatarsal (TMT) joint. The accessory ligament of the deep digital flexor tendon (ALDDFT) is narrow from dorsal to plantar (arrow), well separated from the suspensory ligament (SL), and more echogenic than either the deep digital flexor tendon (DDFT) or the SL. **B,** Transverse ultrasonographic image of the right hindlimb obtained 5 cm distal to the TMT joint. Medial is to the left. Clinically there was palpable edematous swelling in the proximal metatarsal region, medially more than laterally, between the SL and the DDFT. The ALDDFT is enlarged (arrows) with diffuse decrease in echogenicity involving almost the entire ligament, with an anechogenic area medially. There is no longer space between the ALDDFT and the SL.

ALDDFT is less echogenic than the DDFT and suspensory ligament.

With forelimb injury, the ALDDFT invariably is enlarged and tends to expand around the borders of the DDFT, especially laterally. With severe injuries, it may be necessary to move the transducer medially and laterally to evaluate properly the margins of the ligament. Often definition of the borders of the ligament is lost, with a diffuse reduction in echogenicity of the ligament, sometimes with anechogenic areas. Occasionally a large proportion of the ligament is anechogenic. Central core lesions are comparatively rare, although acentric lesions restricted to the lateral border may occur, with the majority of the ligament appearing relatively normal. The dorsal border of the DDFT should be inspected carefully for evidence of concurrent injury, especially in horses with recurrent injury. In horses in which injury has been sustained secondary to previous superficial digital flexor tendonitis or in which desmitis of the ALDDFT is recurrent, the SDFT also should be evaluated for evidence of simultaneous recurrent injury or recent injury. The transducer should be focused on the SDFT, using a standoff. Adhesions between the ALDDFT and adjacent structures may be best identified in longitudinal images obtained with the limb not bearing weight. With passive flexion and extension of the fetlock it should be possible to see independent movement of the SDFT, DDFT, and ALDDFT, provided that no clinically significant adhesion formation has occurred. Concurrent injury of the suspensory ligament is seen rarely in association with desmitis of the ALDDFT. Occasionally, periligamentar echogenic tissue develops because of tearing of surrounding fascia.

In horses with chronic desmitis, when substantial enlargement of the ALDDFT occurs, with or without enlargement of the SDFT, the cross-sectional area of the DDFT often is reduced significantly.¹²

In acute hindlimb injuries in the proximal metatarsal region the ALDDFT should be evaluated from the plantaro-medial aspect of the limb (see Figure 71-3). In horses that initially had an enlarged ALDDFT and inability to load the heel of the affected limb, the ALDDFT usually is enlarged, with poorly demarcated borders, and is diffusely hypoechogenic. Examination can be challenging in cob-types with very thick skin and a dense hair coat, especially if there are areas of dermal fibrosis. It is often necessary to use a transducer with lower frequency (e.g., 8 MHz) and to turn up the gain controls. It is important to be aware of the normal architecture of the ALDDFT because frequently the entire cross-sectional area of the ALDDFT may be diffusely hypoechoic, and if the appearance is bilaterally symmetrical such lesions may be overlooked. Other structures in the metacarpal or metatarsal regions and pastern should be examined, because lesions have been identified simultaneously in the SDFT¹⁶ and the distal sesamoidean ligaments.¹²

TREATMENT

In horses with acute, first-time primary injuries of the ALDDFT, conservative treatment is usually satisfactory, but the prognosis is more guarded for horses with longer-term injuries when horses have continued to exercise. The horse should be restricted to box rest and controlled walking exercise for a minimum of 3 months and then should be reevaluated ultrasonographically. Nonsteroidal antiinflammatory drugs should be given if the horse will not load the limb normally at rest to avoid development of a secondary flexural deformity of the metacarpophalangeal joint. Any foot imbalance should be corrected.

Improvement in echogenicity generally is seen more quickly than in comparable injuries of the SDFT. Box rest and controlled walking exercise should continue until the

ligament is of similar echogenicity to the DDFT in transverse and longitudinal images. Progress should be monitored monthly after the first reevaluation 3 months after injury.

Horses that are allowed uncontrolled turnout in the initial 3-month period tend to have persistent clinical signs, and lesions persist ultrasonographically. Treatment with β -aminopropionitrile fumarate could be considered, especially in horses that have sustained a recurrent injury; however, no published reports of its efficacy in treating this condition are available, although successful results have been achieved, and a licensed product is no longer available.¹² There are also anecdotal reports of successful treatment with fresh bone marrow, platelet-rich plasma, or mesenchymal stem cell therapy. I have treated six horses with chronic forelimb injuries of the ALDDFT with mesenchymal stem cells and the results to date have been extremely promising.

Differences in the reported success of conservative treatment of horses with forelimb injuries of the ALDDFT have been substantial.⁴⁻⁶ A number of factors, including the chronicity of the injury when therapy was first instituted and the type of horse, probably account for this disparity in success. I⁴ reported complete functional recovery in 76% of 27 horses and ponies, whereas McDiarmid⁵ reported only 43% success, and Van den Belt, Becker, and Dik⁶ reported only 18%. Most of the horses in the series of Van den Belt, Becker, and Dik were large Warmbloods, whereas my series⁴ included a large number of ponies. In my experience early recognition and aggressive treatment are key factors to a successful outcome. In a series of 13 horses with acute hindlimb injury in the mid-metatarsal region, 73% returned to full athletic function.¹¹ These were mostly pleasure riding horses. Proximal hindlimb lesions in sports horses have not been well documented; in my experience four of seven horses have returned to their former athletic function.

In horses with chronic, recurrent desmitis, in horses with evidence of adhesions between the ALDDFT and the

SDFT, or in those that tend to stand with the fetlock flexed, surgical treatment by desmotomy of the ALDDFT may be indicated.^{4,7} The treated ligament heals by scar tissue that is inferior in strength to normal ligament, but the ligament will be longer, and this may reduce the strain on it²¹ and thus reduce the risks of reinjury. Experimental removal of a full-thickness piece of the ALDDFT of 1 cm length resulted in long-term repair by scar tissue, in which orientation of the collagen was random. The healed ligaments were 1 cm longer than control ligaments and enlarged in cross-sectional area. The functional characteristics, force, and elongation at failure reached 80% of control values.²²

The number of published long-term follow-up results for treatment of horses with chronic desmitis of the ALDDFT by desmotomy is limited. In my experience desmotomy has been successful in horses with chronic desmitis of the ALDDFT alone, but in those with concurrent superficial digital flexor tendonitis, or a flexural deformity of the metacarpophalangeal joint that cannot be corrected passively, the results have been disappointing. Horses with concurrent superficial digital flexor tendonitis have been relieved of evidence of resting pain, but restoring these horses to full athletic function has not been possible.

Horses with insidious onset of desmopathy of the ALDDFT of one or both hindlimbs have a poor prognosis with conservative treatment.¹¹ Treatment by desmotomy or desmectomy also resulted in persistent lameness in the majority, with preexisting contracture of the fetlock being an extremely poor prognostic indicator.

The prognosis depends on the chronicity of the injury and evidence of any concurrent injury to the DDFT or SDFT. Horses with acute injuries have a better prognosis than those with chronic injuries. Horses with recurrent injuries have a more guarded prognosis, especially if lesions are identified in the DDFT. Horses with lesions of the ALDDFT that have developed secondary to superficial digital flexor tendonitis have the most guarded prognosis, especially if any evidence of flexural deformity exists.

Chapter 72

The Suspensory Apparatus

Sue J. Dyson and Ronald L. Genovese

ANATOMY AND PATHOPHYSIOLOGY

The suspensory ligament (SL) is correctly called the *third interosseous muscle*, but it is referred to as the SL throughout this text. The anatomy in the forelimbs and hindlimbs is similar, and separate mention of the hindlimb is made only when substantial differences exist.

The SL can be divided into three separate regions that are subject to injury: the proximal part, the body, and the branches. For clinical purposes, in the forelimb the proximal part extends from 4 to 12 cm distal to the accessory

carpal bone, and in the hindlimb, from 2 to 10 cm distal to the tarsometatarsal joint. The distal sesamoidean ligaments are considered individually.

In the forelimb the SL originates from two differently shaped lobes that rapidly fuse. In the hindlimb this division is less obvious. The SL contains a variable amount of muscular tissue (2% to 11%), which tends to be bilaterally symmetrical.¹ In the forelimb the SL originates from the palmar carpal ligament and the proximal aspect of the third metacarpal bone (McIII), whereas in the hindlimb it originates principally from the proximoplantar aspect of the third metatarsal bone (MtIII). There is an accessory ligament of the SL that extends proximally and originates on the plantar aspect of the fourth tarsal bone. The SL in the forelimb is approximately rectangular in cross-section, but it is more rounded in the hindlimb. There are also fibers that arise from the axial aspect of the fourth metacarpal bone (McIV).

The body of the SL descends between the second metacarpal or metatarsal bone (McII, MtII) and the McIV or the

fourth metatarsal bone (MtIV) and divides into two branches at a variable site in the midmetacarpal (midmetatarsal) region. The level of division is usually bilaterally symmetrical. Each branch inserts on the abaxial surface of the corresponding proximal sesamoid bone (PSB). Each branch detaches a thin extensor branch dorsodistally that courses obliquely across the pastern to join the dorsal digital extensor tendon just above the proximal interphalangeal joint. Each extensor branch also blends with the corresponding collateral sesamoidean ligament.

The distal sesamoidean ligaments are the functional continuation of the SL in the digit and consist of the straight sesamoidean ligament, oblique sesamoidean ligaments, cruciate sesamoidean ligaments, and short sesamoidean ligaments. All attach proximally to the base of the PSBs and the proximal scutum. The straight sesamoidean ligament is a flat trapezoidal band that inserts via the scutum medium onto the proximal aspect of the middle phalanx. The oblique sesamoidean ligaments are triangular structures that converge to insert on the palmar aspect of the proximal phalanx. The cruciate sesamoidean ligaments form the palmar wall of the distal palmar synovial recess of the metacarpophalangeal joint. They consist of two thin layers of tissue that cross each other and insert on the proximal palmar tuberosities of the proximal phalanx. The short sesamoidean ligaments insert on the proximal palmar aspect of the proximal phalanx and are difficult to separate from the dorsal aspect of the oblique sesamoidean ligaments.

The palmar ligament of the fetlock, also referred to as the *intersemoidean ligament*, is a thick collagen structure that completely covers the palmar and axial surfaces of the PSBs and is strongly attached to them. Together with the PSBs, the palmar ligament forms the proximal scutum. The concave palmar surface of the proximal scutum provides a smooth surface over which the digital flexor tendons glide.

In the forelimb the SL is innervated by the palmar metacarpal nerves, derived from the lateral palmar nerve, which receives fibers from the ulnar and median nerves.² The hindlimb SL is innervated by the plantar metatarsal nerves, branches from the deep branch of the lateral plantar nerve, which is derived from the tibial nerve. The proximal aspect of the SL is closely related to the distal palmar outpouchings of the carpometacarpal joint in the forelimb³ and the plantar outpouchings of the tarsometatarsal joint in the hindlimb.⁴

The principal function of the SL is to prevent excessive extension of the fetlock joint.⁵ During weight bearing the relative tension in the SL and digital flexor tendons regulates the stresses applied to different aspects of the McIII. When a limb is fully load bearing, the distal parts of the SL branches are apposed closely to the abaxial aspects of the metacarpal condyles and then move to the palmar aspect as the fetlock drops. During hyperextension the PSBs move distally and dorsally, so the branches of the SL act as articular surfaces to balance the position of the McIII. If the limb is loaded asymmetrically, so that torque is on the fetlock, the SL branches contribute to joint stability on the side opposite compression of the joint.

Some evidence exists that training increases the strength of the SL; the mean absolute load to failure in a single load-to-failure compression test was significantly higher in horses that were in race training compared with those that

were confined to box or paddock rest.⁶ In the trained group failure was most likely to be by fracture of a PSB, whereas in the untrained group the SL failed. However, when six 2-year-old Thoroughbred (TB) fillies underwent an 18-month controlled exercise program including galloping and were compared with six fillies that were restricted to walking exercise, no differences in the collagen fibril mass-average diameter in the body of the SL were found.⁷ Mass-average diameter is correlated with ligament strength.

PROXIMAL SUSPENSORY DESMITIS IN THE FORELIMB

Proximal suspensory desmitis (PSD) is a common injury in the forelimbs⁸⁻¹² of athletic horses and may occur unilaterally or bilaterally. Some confusion has occurred about what constitutes PSD, and many clinicians have used this term for lameness that is worse with the affected limb on the outside of a circle and that is alleviated by analgesia of the proximal palmar metacarpal region but in which radiological and ultrasonographic findings have been negative. In our experience this case scenario is relatively unusual. Ultrasonographic abnormalities of the proximal SL are usually detectable, and the absence of detectable structural abnormality should alert the veterinarian to search for an alternative diagnosis. However, in a small proportion of horses abnormalities of the SL that were not apparent using ultrasonography have been identified using magnetic resonance imaging (MRI).^{13,14}

PSD usually results in sudden-onset lameness, which can be remarkably transient, resolving within 24 hours unless the horse is worked hard. In horses with more chronic desmitis, lameness may be persistent. Lameness varies from mild to moderate and is rarely severe, unless the lesion is extensive. Lameness in Standardbred (STB) racehorses may be apparent only at high speeds. Bilateral PSD may result in loss of action rather than overt lameness, which occurs more commonly in flat racehorses than other sports horses, probably because of failure to recognize earlier, subtle unilateral lameness. However, dressage horses and event horses may be similarly affected. In a jumping horse the rider's complaint may be of failure of a horse to land with a specific forelimb leading. While ground reaction force is greater in the nonlead forelimb when landing from a fence, the lead forelimb has greater extension of the fetlock, resulting in potentially greater stress on the suspensory apparatus. So with SL injury the horse may be reluctant to land with the lame forelimb leading. Lameness is usually worse on soft ground, especially with the affected limb on the outside of a circle, and when subtle may be more easily felt by a rider than seen by an observer. In some horses lameness is never detectable either in hand or on the lunge and is only apparent when the horse is ridden. Lameness may not be apparent at the working trot but may be detectable at the medium or extended trot. Presumably this reflects increased stress on the SL because of increased extension of the fetlock at extended trot compared with working trot. Recognition of these features in the history may be important, because acute lameness often resolves rapidly, and working the horse hard to reproduce lameness, with the inherent risk of worsening the injury, may be undesirable. Lameness is

often transiently accentuated by distal limb flexion. We believe that this is because the suspensory apparatus is relaxed during flexion and undergoes sudden stretching when the limb is loaded.

In the acute phase slight edema in the proximal metacarpal region, localized heat, and distention of the medial palmar vein may occur, but these features may be transient or absent. Pressure applied to the SL against the palmar aspect of the McIII or forced extension and protraction of the limb may elicit pain, but the absence of pain does not preclude the presence of PSD.

The feet should be evaluated carefully, because frequently foot imbalance is a predisposing factor. Back-at-the-knee and tied-in below the knee conformations also may be predisposing factors.

PSD is a common compensatory injury; therefore the whole horse should be evaluated to ensure that other causes of lameness are not missed. There is a relationship between front foot pain and PSD. PSD can occur in forelimbs and hindlimbs simultaneously.

Diagnostic Analgesic Techniques

If PSD is suspected, perineural analgesia of the lateral palmar nerve using lateral³ or medial¹⁵ approaches (2 mL mepivacaine) or the medial and lateral palmar metacarpal nerves (2 mL per site) is indicated (see Chapter 10). This should result in substantial improvement in, or alleviation of, lameness within 10 minutes, assuming PSD is the only cause of lameness. However, neither technique is necessarily specific. Blockade of the lateral palmar nerve also has the potential to alleviate pain associated with a lateral source of pain in the more distal aspect of the limb (e.g., a splint). The risks of influencing middle carpal joint pain are less than with the subcarpal approach, but with the lateral approach local anesthetic solution may diffuse and improve lameness associated with the middle carpal joint¹⁶ or with the carpal canal. Perineural analgesia of the palmar metacarpal nerves may alleviate pain associated with the middle carpal or carpometacarpal joints because of local diffusion or inadvertent deposition of local anesthetic solution into the distopalmar outpouchings of the carpometacarpal joint capsule. There is no right or wrong method, but it is important to be aware of the limitations of whichever technique is used. One author (SJD) usually blocks the medial and lateral palmar metacarpal nerves using a lateral approach, with the limb non-weight bearing. In a difficult, potentially dangerous horse that strikes out, the lateral palmar nerve is blocked with the limb bearing weight. It is easy to hit the lateral palmar nerve using the medial approach, causing the horse sudden severe pain; therefore this technique is rarely used. A false-negative result may be achieved because of inadvertent injection into the carpal sheath or failure of the local anesthetic solution to diffuse proximally to the most proximal extent of a lesion. Although the SL receives innervation from fibers from the median and ulnar nerves, perineural analgesia of the ulnar nerve usually resolves or substantially improves lameness associated with PSD. However, in a minority of horses perineural analgesia of the median and ulnar nerves is required to abolish lameness completely.

Intraarticular analgesia of the middle carpal joint may result in partial improvement or complete alleviation of pain associated with the proximal aspect of the SL in some

horses (15 [60%] of 25 horses).¹⁶ Using a dorsal approach to the middle carpal joint rather than a palmarolateral approach should theoretically reduce the risks of diffusion of local anesthetic solution to the proximal aspect of the SL and palmar metacarpal nerves; however, in practice the difference seems minor. Comparison of the relative responses to middle carpal analgesia (6 mL mepivacaine; assessed 10 minutes after injection) and perineural analgesia of the lateral palmar nerve or the palmar metacarpal nerves is potentially useful but can be highly misleading. Generally a horse with lameness caused by PSD responds better to perineural analgesia than intraarticular analgesia, but this is not universal. Similarly, primary middle carpal joint pain usually is improved best by intraarticular analgesia, but this is not always the case. Middle carpal joint pain and PSD may occur concurrently, especially in STB and TB racehorses. The clinician should evaluate the response to these diagnostic analgesic techniques in light of the following:

- The use of the horse and thus the likelihood of the site of injury, and other clinical signs
- Other clinical signs: for example, distention of the middle carpal joint capsule and pain on passive manipulation of the carpus
- The degree and character of the lameness

Perineural analgesia of the palmar nerves at the level of the base of the PSBs often results in lameness because of PSD appearing worse. We believe that this reflects some loss of proprioceptive function of the distal aspect of the limb so that the horse is less able to protect the painful SL. Perineural analgesia of the palmar nerves (at midmetacarpal level) and palmar metacarpal nerves (distal to the button of the McII and the McIV) (four-point or low palmar block) often results in some improvement in pain associated with PSD, possibly because of proximal diffusion of local anesthetic solution via lymphatic vessels or along fascial planes. However, a recent contrast study indicated that this may not occur.¹⁷ Perhaps improvement may be due to pain extending further distally in the SL than the site of detectable injury.

More than one source of pain may be contributing to lameness. PSD and concurrent foot pain occur commonly. Hindlimb lameness also may be present, especially in the contralateral hindlimb, so it is important to assess and to reevaluate the whole horse.

Differential Diagnosis

PSD should be differentiated from middle carpal joint pain, being aware that especially in young TB racehorses and STB racehorses lesions may occur in both locations simultaneously. Osteoarthritis of the carpometacarpal joint occasionally occurs (see page 417). Horses with pain associated with palmar cortical fatigue fractures or stress reactions of the McIII^{11,18-20} respond similarly to diagnostic analgesic techniques; however, in horses with fracture, lameness tends to be more severe and worse on firm ground and often deteriorates the farther the horse trots (see page 413). Avulsion fractures of the McIII at the origin of the SL (see page 417) occur less frequently and tend to be associated with more persistent and severe lameness.^{1,21} Pain associated with the carpal sheath or carpal retinaculum also should be considered (see Chapter 75). Perineural analgesia of the deep branch of the lateral palmar nerve or the palmar

metacarpal nerves alone should not alleviate pain associated with the deep digital flexor tendon (DDFT) or its accessory ligament (ALDDFT), the superficial digital flexor tendon (SDFT), or the fetlock region, without simultaneous blockade of the palmar nerves. However, horses with proximal lesions of the SDFT or ALDDFT may show partial improvement in lameness.

Diagnostic Ultrasonography

Diagnostic ultrasonography is essential for accurate diagnosis of PSD. The limb should be evaluated in transverse and longitudinal planes, and careful comparison should be made with the contralateral limb. High-quality images are required, because lesions can be subtle and easily missed if the gain controls are too high or if the transducer is not focused on the SL. Artifacts are readily created if the transducer is not in complete contact with the limb. The contours of the proximal palmar aspect of the metacarpal region can make obtaining longitudinal images difficult, especially because the proximal palmar aspect of the McIII slopes backward. Therefore creating hypoechoic artifacts at the enthesis of the SL on the McIII is easy. Cross-sectional area measurements may be extremely valuable, especially in horses with acute PSD, because enlargement of the ligament may be the only detectable ultrasonographic abnormality. Bear in mind that muscular tissue appears less echogenic than does ligamentous tissue and that proximally the SL originates in two halves. The entire cross-section of the SL cannot be seen from a palmar approach, and marginal lesions may be missed unless oblique images are also obtained. A convex transducer or virtual convex transducer allows a greater proportion of the proximal abaxial aspects of the SL to be evaluated in transverse images compared with a linear transducer. Previous injuries to the SL may not resolve fully to restore normal, uniform echogenicity. Be aware that poor diagnostic analgesic technique may result in aspiration of air, which creates artifacts. This usually resolves in 24 hours. A thin band of the SL passes proximally from the enthesis on the McIII to blend with the palmar carpal fascia. The anechoic space seen dorsal to the SL at this level is fluid in the palmar recess of the carpometacarpal joint and should not be mistaken for a lesion (Figure 72-1).

Abnormalities associated with PSD include the following²² (Figures 72-2 and 72-3):

- Enlargement of the cross-sectional area. This may result in reduction of space between the SL and the palmar cortex of the McIII or reduced space between the SL and the ALDDFT
- Poor demarcation of the margins of the SL, especially the dorsal margin
- Focal or diffuse areas of reduced echogenicity. These may extend less than 1 cm proximodistally and occupy from less than 10% to up to the entire cross-sectional area of the ligament
- Focal anechoic core lesions
- Reduced strength of fiber pattern
- Focal fibrosis or mineralization (rare in acute injuries)
- Mild increased echogenicity of the entire SL in long-term, chronic injuries
- Entheseous new bone on the palmar aspect of the McIII

Fig. 72-1 • Longitudinal (proximal is to the left) ultrasonographic image of the proximal metacarpal region. The thin echogenic band from the suspensory ligament (SL) passes proximally from the enthesis of the suspensory ligament on the third metacarpal bone to blend with the palmar fascia. Dorsal to the suspensory ligament is anechoic fluid within the palmar recess of the carpometacarpal joint capsule (arrow).

In a horse with bilateral PSD an obvious lesion may be detectable in the lamer limb, but abnormalities may be much more subtle and occasionally not apparent in the less lame limb. In a 3-year-old TB that sustains PSD at 2 years of age, mild lameness may be recurrent, and discerning any structural abnormality other than enlargement of the SL may not be possible.

The degree of ultrasonographic abnormality (cross-sectional area involved and proximodistal extent of the lesion) usually reflects the severity of the lameness. In horses with acute PSD the ultrasonographic abnormalities may be subtle, although if lameness is unilateral, slight enlargement of cross-sectional area may be detectable. Care should be taken to compare measurements in the contralateral limb at the same distance distal to the accessory carpal bone. Ultrasonographic abnormalities may worsen over the next 10 to 14 days, and reevaluation may be useful to confirm the diagnosis.

In horses with an avulsion fracture of the McIII at the origin of the SL, the fracture fragment is usually readily identifiable and generally is associated with only a focal lesion in the SL itself, usually restricted to the dorsal aspect (see page 417).

Radiography and Radiology

Because of the potential nonspecificity of local analgesic techniques I recommend radiographic examination of the carpus and proximal metacarpal region using at least flexed lateromedial, dorsolateral-palmaromedial oblique, dorso-medial-palmarolateral oblique, and dorsopalmar images. In racehorses, endurance, and event horses a skyline image of the third carpal bone may also be required. Usually no detectable radiological abnormalities of the McIII occur in horses with acute PSD. With chronic PSD, a generalized area of increased opacity of the proximal aspect of the

Fig. 72-2 • **A**, Transverse ultrasonographic image of the metacarpal region of a 3-year-old Thoroughbred, with mild forelimb lameness, at 9 cm distal to the accessory carpal bone. The suspensory ligament (SL) shows a slight overall reduction in echogenicity compatible with proximal suspensory desmitis. The ligament is enlarged (cross-sectional area 1.39 cm² compared with 1.25 cm² in the contralateral limb). The lesion extended less than 1 cm proximodistally. **B**, Transverse ultrasonographic image of the metacarpal region at 8 cm distal to the accessory carpal bone of the right forelimb of a 7-year-old medium-level dressage horse. The entire cross-sectional area of the SL is reduced in echogenicity. The lesion extended 1.5 cm proximodistally. Note also the hyperechoic appearance of the accessory ligament of the deep digital flexor tendon (ALDDFT). **C**, Transverse ultrasonographic image of the proximal metacarpal region of a 6-year-old event horse with acute-onset right forelimb lameness. There is a hypoechoic lesion in the medial aspect of the SL that extends less than 1 cm proximodistally. Medial is left. **D**, Transverse ultrasonographic image of the right forelimb of a 7-year-old dressage horse with bilateral forelimb lameness. The palmar aspect of the SL is slightly increased in echogenicity, but the dorsal aspect is diffusely hypoechoic.

McIII may be seen in dorsopalmar images. This increased radiopacity should be differentiated from that associated with a palmar cortical fatigue fracture,²³ which is invariably medial. A focal linear region of increased opacity may reflect the presence of an enthesioid spike. In a lateromedial image subcortical endosteal reaction in the proximal palmar aspect of the McIII may be apparent. These secondary bony changes (endosteal and enthesioid new bone) in

a forelimb reflect chronicity of the injury and are associated with a more guarded prognosis.

Nuclear Scintigraphy

Reports in the literature about the usefulness of nuclear scintigraphy for diagnosing PSD are confusing because of failure to correlate scintigraphic findings with ultrasonographic and radiological findings and because avulsion

Fig. 72-3 • **A**, Transverse ultrasonographic image of the proximal metacarpal region at 8 cm distal to the accessory carpal bone of the left forelimb of a Grand Prix show jumper. The horse had developed acute severe lameness immediately after completing a jumping round 2 weeks previously. The dorsal half of the suspensory ligament is diffusely hypoechoic. **B**, Longitudinal ultrasonographic image of the proximal metacarpal region of the same horse. Proximal is to the left. The dorsal aspect of the suspensory ligament is diffusely hypoechoic.

fractures of the McIII were not considered separately.^{24,25} Nuclear scintigraphy is generally unnecessary for diagnosing PSD, provided that good-quality ultrasonographic images are obtained, but may give additional information about associated bone turnover at the origin of the SL. Pool and bone phase images may be negative. Abnormal radiopharmaceutical uptake in the pool phase may actually reflect early bone uptake. Increased uptake of ^{99m}Tc-methylene diphosphonate was identified in the proximal palmar aspect of the McIII in approximately 6% of 40 horses with ultrasonographic evidence of PSD.²⁶ Therefore negative scintigraphic images do not preclude the presence of PSD. The presence of increased radiopharmaceutical uptake (IRU) reflecting entheses injury is usually associated with more severe lameness that takes longer to resolve. IRU associated with either an avulsion fracture of the McIII at the insertion of the SL or a stress fracture is likely to be more intense. IRU in the bone phase, seen in the absence of ultrasonographic and radiological abnormalities, is more likely to reflect a primary pathological condition of bone.

Magnetic Resonance Imaging

MRI is usually not necessary for the diagnosis of PSD but should be considered if no ultrasonographic abnormality can be identified.^{13,14} Interpretation is confounded by the presence of variable amounts of muscle and adipose tissue in the center of each lobe of the SL, which has high signal intensity.^{27,28} Increased signal intensity in the surrounding ligamentous tissue reflects injury and may be accompanied by enlargement of the SL and sometimes adhesions to the McII, McIII, and McIV. However, it is important to recognize the normal fibers of the SL, which originate from the axial aspect of the McIV extending up to 7 cm distal to the carpometacarpal joint.²⁸ MRI may be more sensitive than ultrasonography for identification of entheses new bone and endosteal reaction at the ligament's origin. MRI is the

most accurate method of detection of syndesmoathy between the McIII and either the McII or the McIV, which is an unusual but important differential diagnosis. It is also valuable for the detection of primary bone trauma of the McIII.

Computed Tomography

Computed tomography (CT) or contrast-enhanced CT can also be useful for the diagnosis of PSD and entheses new bone.

Treatment

Most horses with acute forelimb PSD respond well to box rest and controlled walking exercise for 3 months.^{29,30} Uncontrolled turnout is contraindicated. Attention to correct foot balance is important. Elevation of the heel is contraindicated because it increases load on the SL. A premature resumption of work usually results in recurrent injury. Approximately 90% of horses resume full athletic function without recurrent injury.¹ In the early period after return to work circumstances that create hyperextension of the fetlock should be avoided. For example, dressage horses should avoid medium and extended trot. Attention should also be paid to the footing on which the horse works. Horses with chronic PSD may require more prolonged rehabilitation, and in a small proportion lameness is persistent. If low-grade residual lameness persists after 3 to 6 months but serial ultrasonographic examinations reveal no change in echogenicity, then introduction of trotting exercise sometimes stimulates further repair and resolution of lameness. Some TB racehorses with chronic lesions have been able to be maintained in training with judicious use of phenylbutazone, without clinically significant deterioration of the lesion. No fatalities associated with PSD occurred in 630 TB racehorses examined post mortem because of musculoskeletal injuries.²⁹ Some STB

racehorses with acute lesions have been managed by slightly reducing the training schedule, administering local injections of corticosteroids and hyaluronan, using symptomatic antiinflammatory therapy (local icing, liniments such as dimethyl sulfoxide [DMSO] and corticosteroid paints, and phenylbutazone as necessary), and shortening the toes and increasing hoof angle. Although a few treated horses were able to race successfully, prognosis after rest was better.²⁹

Extracorporeal shock wave treatment or radial pressure wave therapy (three treatments at 2-week intervals) was successful in some horses with chronic lesions that had failed to respond to conservative management.^{31,32} Ten (50%) of 20 horses with chronic forelimb PSD with lameness of greater than 3 months' duration were in full work 6 months after treatment.³² Repeated long-term treatments are sometimes required. Local infiltration with 4 to 6 mL of 2% iodine in almond oil has been used successfully.⁸

In some horses the lesions disappear completely ultrasonographically. In others echogenicity may increase, but uniform echogenicity is never restored. Rest should be continued until the ultrasonographic appearance remains stable.

Surgical splitting of the SL has been used in some horses with PSD with successful results in some horses; however, the results have been unpredictable.^{14,33} There are currently no long-term, peer-reviewed studies of the results of injection of pigs' urinary bladder matrix, mesenchymal stem cells, or other biological agents such as platelet-rich plasma, although anecdotally successful results have been reported. In sports horses with chronic injuries that have failed to respond to conservative management, one author (SJD) has successfully used either mesenchymal stem cells or desmoplasty combined with injection of platelet-rich plasma.

PROXIMAL SUSPENSORY DESMITIS IN THE HINDLIMB

PSD in the hindlimb results in either an insidious or a sudden-onset lameness that may be mild or severe. Some horses show poor performance rather than a recognized lameness. In contrast to the forelimb, lameness may persist and remain severe, despite restriction to box rest. Such persistence probably is caused by a compartment-like syndrome and pressure on the adjacent plantar metatarsal nerves.^{34,35} In view of the chronicity of some lesions when first identified and the finding of secondary radiological changes in sound horses, some lesions likely exist subclinically or are associated with a low-grade lameness that goes unrecognized. The incidence of bilateral lesions is higher than in forelimbs.

PSD in the hindlimb occurs in horses in all athletic disciplines and of all ages and is a particular problem in dressage horses.³⁶ There is an association between straight hock conformation and hyperextension of the metatarsophalangeal joint and hindlimb PSD (Figure 72-4). Such conformational abnormalities were identified in nine (21%) of 42 horses with hindlimb PSD but in only four (8%) of 50 horses examined consecutively with hindlimb lameness unrelated to the suspensory apparatus.³⁷ Straight hock conformation may predispose to PSD or develop secondarily; hyperextension of the metatarsophalangeal joint

Fig. 72-4 • The hindlimbs of a 7-year-old show jumper with proximal suspensory desmitis of the right hindlimb. Note the relatively straight hock conformation and the sloping pasterns associated with hyperextension of the hind fetlocks. The horse also has rather low heels and long toes.

may develop as a sequela to PSD, probably as the result of progressive degeneration of the SL. A long-toe and low-heel conformation also may be a predisposing factor, especially if associated with abnormal orientation of the distal phalanx, with the plantar aspect lower than the toe.²⁹

PSD in the hindlimb in a STB racehorse is common and usually results in an abnormal gait at high speeds, which may or may not be apparent at the trot. Unilateral left hindlimb lameness may manifest as the horse drifting to the right shaft and being on the left line and vice versa.

Horses with acute hindlimb PSD may have localized heat and swelling and pain on pressure applied to the SL, but frequently no localizing clinical features are apparent.

Lameness is often characterized by a reduced height of arc of foot flight, with or without intermittent catching of the toe. There may be reduced extension of the metatarsophalangeal joint unless the functional integrity of the SL is compromised. The cranial phase of the stride may be shortened. Lameness may be accentuated by proximal or distal limb flexion. Bilateral lesions may result in poor hindlimb action rather than obvious hindlimb lameness. Performance horses may not be overtly lame in hand, but when ridden show reduced hindlimb impulsion, difficulties in transitions, stiffness, resistant behavior, evasions such as bolting, difficulties in turning or stopping, reluctance to perform certain dressage movements, or reduced power when jumping. Lameness may be more obvious on a circle on the lunge, but unlike in forelimb PSD the lameness is not necessarily worse with the lamer limb on the outside. Approximately 50% of horses with hindlimb PSD are lamer with the affected limb on the outside or inside of a circle. As with many horses with hindlimb lameness, lameness is often more obvious when the horse is ridden,

especially when the rider sits on the diagonal of the lame or lamers limb.

Diagnostic Analgesic Techniques

Perineural analgesia of the plantar nerves (midmetatarsal level) and plantar metatarsal nerves may result in slight improvement in lameness because of proximal diffusion of the local anesthetic solution or distal extension of pain in the SL, or concomitant injury of a SL branch. Lameness usually is improved substantially by perineural analgesia of the medial and lateral plantar metatarsal nerves (2 mL of mepivacaine 2% per site) or the deep branch of the lateral plantar nerve distal to the tarsus, but lameness may not be alleviated fully. Improvement is usually seen within 10 minutes of injection. Critical evaluation of the degree of improvement is considered essential if considering treatment by neurectomy of the deep branch of the lateral plantar nerve. If there is a component of enthesesous pain, this may result in only partial improvement in lameness, which is further improved by deep infiltration of local anesthetic solution toward the plantar aspect of the MtIII. PSD may occur together with pain associated with the tarsometatarsal joint, and if lameness is improved but not abolished by subtarsal analgesia, addition of intraarticular analgesia of the tarsometatarsal joint may abolish the lameness. False-negative results also may be obtained because of inadvertent injection into the tarsal sheath or the tarsometatarsal joint capsule. Subtarsal analgesia can influence tarsometatarsal joint pain, and occasionally (two [8%] of 24 horses³⁴), intraarticular analgesia of the tarsometatarsal (TMT) joint alleviates pain associated with PSD. It is also important to recognize that improvement in lameness after perineural analgesia of the deep branch of the lateral plantar nerve is not synonymous with PSD. There may be other causes of pain, improvement of which results in improvement in lameness. However, an improvement in lameness of 85% or more is usually associated with PSD. Nonetheless, I recommend comparing the response with the effect of intraarticular analgesia of the TMT joint. Perineural analgesia of the tibial nerve alone alleviates pain associated with PSD without substantially influencing tarsal pain. However, the tibial nerve is large; therefore 20 minutes may pass before analgesia is achieved effectively. In horses with bilateral hindlimb stiffness or lack of hindlimb impulsion, best improvement may be seen after perineural analgesia of the deep branch of the lateral plantar nerve performed bilaterally simultaneously. Some horses have secondary sacroiliac joint region pain, and the rider may complain of persistent lack of hindlimb power unless this region is also blocked.

Diagnostic Ultrasonography

High-quality ultrasonographic images are essential for accurate diagnosis, but are not always possible to achieve because of the shape of the limb, position of blood vessels, and the presence of other artifacts. The proximal aspect of the SL should be examined from the plantaromedial aspect of the metatarsal region to evaluate as much of the cross-sectional area as possible. Large vessels plantarolateral to the SL may result in broad linear anechoic artifacts within the SL (Figure 72-5). In large Warmblood horses in particular the SL is situated deeply, and the ultrasound transducer must be focused accordingly. In transverse and

Fig. 72-5 • Transverse ultrasonographic image of the proximal metatarsal region of a horse with proximal suspensory desmitis. Medial is to the left. The narrow anechoic band through the suspensory ligament (*arrow-head*) is an artifact caused by the overlying plantar vessel. The suspensory ligament has a diffuse reduction in echogenicity.

longitudinal images the most proximal part of the SL in a normal horse may appear slightly less echogenic than the DDT (Figure 72-6). Detection of subtle abnormalities requires careful comparison with the contralateral limb, bearing in mind that lesions may be bilateral, and measurement of cross-sectional area or dorsoplantar thickness. Cross-sectional area measurements underestimate real size because the ligament cannot be imaged in its entirety proximally. The SL should be imaged routinely in transverse and longitudinal planes. The shape of the proximoplantar aspect of the metatarsal region influences how easy it is to obtain high-quality images. Use of a standoff pad can provide a larger contact area and thereby enhance image quality in some horses. Acquisition of transverse images using either a convex array or a virtual convex transducer may permit evaluation of more of the mediolateral extent of the SL than using a linear transducer. It is also important to recognize that injury may be localized to either the medial or the lateral aspect of the SL.

In hindlimb PSD focal anechogenic areas are relatively unusual, except in the STB racehorse. More commonly the SL is enlarged, with poor demarcation of its borders and a diffuse reduction in echogenicity of part or all of the cross-sectional area of the ligament (see Figure 72-5) (Figure 72-7). Fibrosis or ectopic mineralization occurs more often in hindlimbs than in forelimbs. An irregular contour of the plantar aspect of the MtIII may reflect enthesophyte formation. In some horses, especially those with abnormal conformation, the lesions may progress despite box rest.

Occasionally there are concurrent injuries of the SL branches, especially in horses with abnormal conformation, and consideration should be given to routine evaluation of the SL in its entirety.

Radiography and Radiology

Distal hock joint pain and PSD may coexist, so it is recommended that a comprehensive radiographic examination

Fig. 72-6 • **A**, Transverse ultrasonographic image of the proximal metatarsal region of a normal horse, 4 cm distal to the tarsometatarsal joint. Medial is to the left. The suspensory ligament is similar in echogenicity to the deep digital flexor tendon. **B**, Longitudinal ultrasonographic image of the proximal metatarsal region of a normal horse. Proximal is to the left.

Fig. 72-7 • Transverse (**A**) ultrasonographic image at 4 cm distal to the tarsometatarsal joint and longitudinal image (**B**) of the left, proximal metatarsal region of an 11-year-old show jumper with left hindlimb lameness caused by proximal suspensory desmitis. The damaged suspensory ligament is diffusely hypoechoic dorsomedially (*arrows*) with diffuse loss of fiber pattern in the longitudinal image. The overlying blood vessel is dilated.

of the hock and proximal metatarsal region is performed using four standard images. Diagnosis should never be based on radiology alone, because some sound horses have some increased radiopacity of the proximal aspect of the MtIII (see Figure 43-2). In horses with chronic active PSD this tends to be more extensive. In the dorsoplantar image, increased opacity of the proximal aspect of the MtIII is often more obvious laterally. In a lateromedial image subcortical increased radiopacity and alteration of the trabecular pattern of the proximoplantar aspect of the MtIII may be caused by endosteal new bone, extending up to

4 cm proximodistally (Figure 72-8). The plantar cortex may itself be thickened, and in addition enthesophyte formation may be visible on the plantar aspect. However, in some horses with acute injury no radiological abnormality is detectable. Radiology is also important to identify osteoarthritis of the distal hock joints, which may be contributing to pain and lameness.

Nuclear Scintigraphy

Nuclear scintigraphy is not a sensitive means of detecting PSD in hindlimbs.²⁶ Pool phase images have been found to

Fig. 72-8 • Lateromedial radiographic image of the right hindlimb of a 7-year-old dressage horse with chronic proximal suspensory desmitis. The proximoplantar aspect of the third metatarsal bone (arrows) has increased subcortical radiopacity.

Fig. 72-9 • Lateral scintigraphic image of the left hindlimb of a 9-year-old Warmblood show jumper with proximal suspensory desmitis. There is marked focal increased radiopharmaceutical uptake in the proximoplantar aspect of the third metatarsal bone.

be positive in only 12% of 46 horses with ultrasonographic evidence of PSD. In bone phase images, IRU in the proximoplantar aspect of the MtIII was found in 12% of 82 horses (Figure 72-9). IRU was associated with more severe ultrasonographic lesions. IRU in the proximoplantar aspect of the MtIII, with no detectable ultrasonographic abnormality of the SL and no radiological change associated with

enthesopathy, may be associated with a primary pathological condition of bone, such as bone trauma or enthesoseous reaction at the origin of the SL, which has been demonstrated using MRI.

Magnetic Resonance Imaging and Computed Tomography

Lesions of the proximal aspect of the SL that were not evident on ultrasonography have been identified with MRI^{13,14,38,39} or computed tomography. MRI has also identified adhesions to the MtII and to the MtIV (Figure 72-10, A) and endosteal and enthesoseous reactions at the ligament's origin (Figure 72-10, B).

Differential Diagnosis

PSD should be differentiated from pain associated with the tarsometatarsal joint, an avulsion fracture of the MtIII at the origin of the SL, primary stress reactions in the MtIII, bone trauma, and syndesmodopathy between the MtIII and either the MtII or the MtIII.

A recent study compared the results of ultrasonography and MRI in 46 limbs of 38 horses in which lameness was improved at least 60% by perineural analgesia of the deep branch of the lateral plantar nerve. Using MRI as the gold standard, 21 limbs had PSD, including nine with osseous abnormalities of the MtIII; four horses had osseous injury at the origin of the SL as the only abnormality.³⁹ However, in nine limbs there were injuries unrelated to the SL, including OA of the distal tarsal joints, enthesopathy of an intertarsal ligament, and osseous pathology of the central or fourth tarsal bones or the MtIII in a variety of locations. No diagnosis was reached for the cause of lameness in 12 limbs. It was suggested that neuropathy of the deep branch of the lateral plantar nerve could possibly be the source of pain in these 12 horses. Ultrasonography had a moderate sensitivity (0.77) and low sensitivity (0.33) for diagnosis of PSD with MRI as the gold standard, with both false-positive and false-negative results.

Treatment

The prognosis for horses with PSD in the hindlimb with conservative management generally has been poor. Only six (14%) of 42 horses seen in a referral practice were able to resume full work without detectable lameness for at least 1 year; all six had been lame for less than 5 weeks.³⁷ All these horses showed substantial improvement in clinical signs within 3 months of the onset of lameness. Two additional horses resumed full work but developed lameness in another limb. Seven horses improved greatly and were able to work, despite persistent mild lameness. Twenty-four horses (57%) had persistent or recurrent lameness. Results from a first opinion practice also were disappointing, with only 10 (59%) of 17 horses resuming work.¹

Horses with acute (less than 4 to 6 weeks' duration) hindlimb PSD respond reasonably well to local infiltration with corticosteroids, aimed at reducing inflammation and therefore swelling and thus minimizing the risk of developing a compartment syndrome (see the following discussion). Foot imbalance is corrected and egg bar shoes are used to reduce extension of the fetlock. Horses with chronic PSD have a guarded prognosis regardless of the treatment. Lameness often tends to persist unchanged, even after

Fig. 72-10 • A, Transverse T2* gradient echo low-field magnetic resonance image of the proximal metatarsal region of a 6-year-old show jumper. Lateral is to the right. There are adhesions between the suspensory ligament and the axial aspect of the fourth metatarsal bone and the plantar aspect of the third metatarsal bone (MtIII) (arrows). **B,** Sagittal short tau inversion recovery (STIR) magnetic resonance image of the left hindlimb of a 3-year-old Thoroughbred flat racehorse with mild architectural abnormalities of the suspensory ligament origin detected ultrasonographically. The horse exhibited severe lameness. There is diffuse increased signal intensity in the proximo-plantar aspect of the MtIII at the origin of the suspensory ligament.

prolonged box rest, which is unusual for a primary soft tissue lesion. In some horses lesions are progressive. Local infiltration with corticosteroids, polysulfated glycosaminoglycans, hyaluronan, or homeopathic drugs such as Actovegin and Traumeel has given disappointing results.

In some horses an initial improvement in lameness is seen after box rest and controlled walking exercise for 2 to 3 months, and then no further improvement is seen. Increasing the exercise despite the lameness sometimes results in further improvement. Some horses have worked satisfactorily while being treated with phenylbutazone, without apparent deterioration of clinical signs or ultrasonographic abnormalities. This indicates that in some horses the SL is able to withstand load and the horse can work satisfactorily provided that pain is controlled.

Extracorporeal shock wave therapy or radial pressure wave therapy appears to be helpful in some horses.³² Eighteen of 30 horses with PSD in forelimbs or hindlimbs were in work 6 months after treatment. Eighteen (40%) of 45 horses with unilateral or bilateral chronic (lameness of greater than 3 months' duration) hindlimb PSD were in full work 6 months after treatment³²; however, a small proportion of these horses have experienced recurrent lameness subsequently. Horses with mild or moderate ultrasonographic lesions responded better than those with severe lesions. Injection of 2% iodine in almond oil resulted in 12 (55%) of 22 horses returning to work.²⁹

Tibial neurectomy performed in eight horses enabled six to return to full athletic function (show jumping and horse trials) for at least 2 years after surgery, with no postoperative complications.¹⁴ Neurectomy of the deep branch of the lateral plantar nerve has been combined with incising the thin fascial covering of the plantar aspect of the SL and was successful in 79% of 200 horses,⁴⁰ 91% of 84

horses,⁴¹ and 62.5% of 16 horses.³⁵ It has also been combined with osteostixis.^{40,42} A further 70% of 120 horses treated by one author (SJD) have returned to full athletic function after neurectomy of the deep branch of the lateral plantar nerve, but two horses experienced deterioration because of progressive lesions in the SL.¹⁴ Both of these horses had preexisting excessively straight hock conformation and/or hyperextension of the fetlock of the lame limb. This has also been reported elsewhere,⁴³ and these conformational abnormalities are considered to be contraindications for surgery.

Postoperative management depends on the severity of the initial injury. Improvement in ultrasonographic appearance is generally seen by 2 months postoperatively, but this may in part reflect neurogenic muscle atrophy. Although some horses may successfully return to work at this stage, horses with severe injuries and those with osseous pain may need a considerably longer rehabilitation period. The presence of IRU associated with PSD usually indicates that a prolonged convalescence will be required. Neurectomy may result in atrophy of the muscle component of the SL, which could potentially influence its function.⁴⁴ The SL is closely related anatomically to the distal hock joints by its accessory ligament. Horses with low-grade residual lameness may respond to intraarticular medication of the distal hock joints.

Fasciotomy of the deep plantar metatarsal fascia has been successful in some horses.¹⁴ Injection of about 30 mL of bone marrow also is claimed to be successful, especially if combined with fasciotomy, allowing 85% of horses to return to the former level of function¹⁴ (see also Chapter 73). Injection of platelet-rich plasma or mesenchymal stem cells has also been combined with fasciotomy, but without neurectomy and anecdotally is successful.

Gross Pathological and Histopathological Findings

Postmortem examinations have been performed on both hindlimbs of eight horses, six with unilateral lameness and two with bilateral lameness.^{22,34} Abnormalities of the SLs were confined to the lame limbs. The SLs were grossly enlarged, with thickening of surrounding fascia and periligamentous tissues, especially on the plantar aspect. Histological changes in the SL included hypercellularity and acellular areas; hemosiderin deposition; fibrosis; hyalinization of collagen; an increased number of fibrous septae, some with blood vessels; neovascularization; and chondroid metaplasia. Although chondroid metaplasia was seen at the ligament-bone interface in lame and sound limbs, intraligamentous chondroid metaplasia was seen only in the lame limbs. These histological abnormalities are consistent with degenerative rather than inflammatory changes.

Evidence of compression of adjacent peripheral nerves was found in the lame limb of five horses.^{22,34} Abnormalities of the plantar metatarsal nerves included thickening of the perineurium, perineural fibrosis, reduction or absence of nerve fibers, and Renaut bodies. Similar abnormalities have been identified in the deep branch of the lateral plantar nerve bilaterally in 11 bilaterally lame horses and unilaterally in the lame limb of five unilaterally lame horses.³⁵

These changes support the theory that PSD in the hindlimb results in a compartment syndrome and some pain may possibly be neuropathic in origin.

AVULSION FRACTURES OF THE THIRD METACARPAL OR METATARSAL BONE AT THE ORIGIN OF THE SUSPENSORY LIGAMENT

Avulsion fractures of the third metacarpal or metatarsal bone at the region of the SL are discussed on page 417.

SUSPENSORY DESMITIS: BODY LESIONS

Desmitis of the body of the SL is principally an injury of horses that race, STBs and TBs (flat racehorses and jumpers). In TBs in Europe the incidence is much higher in horses that race over fences (National Hunt Racing and point to pointing; see Chapter 112) compared with flat racehorses. Although PSD and desmitis of the medial and/or lateral branches of the SL are relatively common injuries in event horses, show jumpers, dressage horses, and endurance horses, body lesions are recognized less frequently, except as associated with an exostosis of the McII or the MtIV (the splint bones) or as a sequela to a branch injury. Injuries occur in forelimbs and hindlimbs, and in STBs several limbs may be affected concurrently, whereas in TBs lesions generally are restricted to the forelimb.^{29,45} There is frequently a poor correlation between the extent of the lesions and the degree of lameness. Performance, however, can be compromised despite lack of evidence of overt lameness. In STB racehorses lameness may be observed or tolerated while athletic function continues. This continued exercise may result in progressive injury or injury to other tendinous or ligamentous structures.

Soreness on palpation of the SL is not synonymous with structural damage. Event horses frequently have

sore SLs for several days after fast work or competition, but rarely does this appear to be associated with a clinically significant problem. Soreness does not appear to be a warning sign of impending desmitis. Upper-level show jumpers may have a sore forelimb SL the day after competition, which often highlights overload caused by lameness in another limb.

Clinical Signs

The clinical signs associated with suspensory body desmitis vary in presence and degree and include the following:

- Localized heat
- Periligamentous edema; severe periligamentous soft tissue swelling may make accurate palpation of the SL difficult
- Rounding of the margins of the SL
- Enlargement of the body of the SL
- Pain on palpation of the margins of the SL
- Abnormal stiffness of the SL
- Pain on palpation of the distal third of the McII or the MtIV, if there is a concurrent fracture
- Lameness; absence of lameness does not preclude clinically significant desmitis
- Hyperextension of the fetlock joint (fetlock drop); in the hindlimb, straight hock conformation

Diagnosis

Diagnosis is based on clinical signs and ultrasonographic assessment. Diagnostic analgesic techniques rarely are required unless another contributory cause of lameness or recurrence of previous desmitis is suspected. In a horse with previous desmitis a previously enlarged SL may have no detectable change in size, shape, or reaction to palpation. Perineural analgesia of the palmar metacarpal nerves proximal to the site of the suspect lesion should remove associated lameness.

The body of the SL of a normal horse is not always uniform in echogenicity because of variable amounts of muscle tissue in the ligament and variations in the level of bifurcation of the SL between horses. This can make detection of subtle lesions difficult. The maximum injury zone is frequently at the region of the bifurcation of the SL, which may appear hypoechogenic in normal horses (Figure 72-11). Careful comparison with the contralateral limb may help if clinical signs are unilateral. Ultrasonographic abnormalities associated with active desmitis include the following:

- Enlargement of the body of the ligament in transverse and median planes
- Loss of definition of one or more of the margins of the ligament
- Focal hypoechoic areas, peripheral or central, extending a variable distance proximodistally
- A diffuse reduction in echogenicity of some or all of the cross-sectional area of the ligament
- In horses with chronic desmitis, focal hyperechoic areas representing fibrosis or mineralization.

Enlargement may be the only detectable abnormality. Careful comparison with the contralateral limb can be helpful. Reference can be made to studies of sizes in normal horses of similar breed, but caution is urged because notable differences do exist between U.S. and European TBs. The extent of ultrasonographic abnormality is not always

Fig. 72-11 • Transverse ultrasonographic image of a normal forelimb suspensory ligament at the level of the beginning of the bifurcation, 18 cm distal to the accessory carpal bone. The central, less echogenic region should not be mistaken for a lesion.

correlated with the severity of clinical signs. A reasonable correlation exists with the severity of the ultrasonographic grade of the injury and the prognosis; however, a diffuse reduction in echogenicity of the cross-sectional area is also associated with a poor prognosis. Lesions may extend into the branches, which should also be examined by ultrasonography.

Many lesions persist long term, although focal lesions in STBs may fill in. In TBs a readily detectable defect often persists, despite some increase in echogenicity and slight reduction in size. This can limit the value of serial ultrasonographic evaluations to determine when a horse might be able to withstand work. Determining objectively to what extent healing has taken place and the strength of the repair tissue often is not possible. This may explain the high rate of recurrence of body lesions in STBs and TBs. Racing careers of STBs can usually be extended, whereas managing TBs is much more difficult, because lameness in TBs rarely stabilizes.²⁹ Horses with slight lesions may be responsive to symptomatic treatment, and a horse may train and race well; however, the lesion is likely to be progressive. The risk of catastrophic breakdown of the suspensory apparatus must always be considered in a TB racehorse. In STB racehorses rest for about 3 months may confer no extra advantage to symptomatic treatment and continued training³⁰ with respect to racing performance. Lesions are usually progressive, and periodic ultrasonographic monitoring is recommended.

There is a high rate of reinjury to the body of the SL of the same or the contralateral limb or to a branch of the same or the contralateral limb subsequent to desmitis of the body of the SL.²⁹

Radiographic examination of the McII and the McIV is indicated if clinical examination suggests abnormal

modeling or a fracture, because surgical amputation may be indicated²⁹ (see page 421).

Management

Treatment is aimed at reducing inflammation by the administration of systemic nonsteroidal antiinflammatory drugs (NSAIDs), local or systemic corticosteroids, hydrotherapy, and controlled exercise. Cryotherapy is used by some clinicians to provide pain relief, but a real risk of progressive deterioration of the lesion exists (see Chapter 89).

Progress is monitored clinically and by serial ultrasonographic examinations. Ideally there should be progressive reduction in cross-sectional area, improvement in echogenicity and fiber alignment, no restrictive periligamentous fibrosis, and reasonable stability in all of these features as exercise is increased. In STBs handwalking exercise is advocated for the first 4 weeks.²⁹ Provided that some improvement in the ultrasonographic appearance of the ligament occurs and the horse is sound when jogged in hand, the horse is harnessed and walked in the jog cart for another 4 weeks. Flat shoes are preferred. The horse is reassessed by ultrasonography after 8 weeks, and if further filling in of the defect occurs, short slow jogging is reintroduced and gradually increased. A third ultrasonographic examination is performed after 8 weeks of jogging, and provided that the lesion is uniformly echogenic to the remainder of the SL and has a linear arrangement of fibers, normal jogging and speed work are resumed. Although this method is successful in some STBs, in others a longer period of convalescence is required.

Continued medical therapy includes daily hydrotherapy—for example, whirlpool boots, stable and exercise bandages, massage with emollient oils, leg sweats, and leg tighteners with or without DMSO. The aim is to stimulate circulation, reduce inflammation, and provide pain relief. The work program should be adapted so that days of light work are interspersed with hard work. Swimming is a useful method of maintaining cardiovascular fitness but should not be used alone, because the musculoskeletal system requires regular stimulation to avoid other injuries.

Intralesional treatment with β -aminopropionitrile fumarate has been used in STB and TB racehorses with moderate to severe injuries of the SL body³⁰; however, a licensed product is no longer available. Eleven of 18 horses successfully returned to racing, although some dropped in class. A recent *in vitro* study compared the potential for various blood-based biological products to induce SL regeneration and indicated that bone marrow aspirates were potentially superior to platelet-rich plasma.⁴⁶ However, nine of nine STB racehorses treated by intralesional injection of platelet-rich plasma returned to racing, with similar performance to that of control horses for 2 years after treatment.⁴⁷ It is important to note, however, that STBs have a much higher tolerance of SL injuries than TBs.

Surgical splitting of the body of the SL usually is not advocated in STBs or TBs.²⁹ However, occasionally, large chronic lesions with associated McII or McIV fractures are split, combined with surgical removal of the fracture piece in STB and, less commonly, TB racehorses. Pin firing combined with rest may be of benefit in some horses with chronic desmitis²⁹ (see Chapter 88).

Fig. 72-12 • Transverse ultrasonographic image of the midmetacarpal region of a 7-year-old show jumper with intermittent left forelimb lameness associated with localized enlargement of the axial aspect of the second metacarpal bone (a splint). Slight pain could be elicited by pressure. Separating the axial border of the bone from the suspensory ligament by palpation was not possible. Lameness was alleviated by local infiltration of local anesthetic solution. Echogenic material (*arrowheads*) extends from the medial aspect of the suspensory ligament, which was slightly hypoechoic dorsomedially. Surgical exploration revealed a loose spicule of bone adjacent to the splint and a granulomatous reaction between it and the suspensory ligament. A focal defect was found in the medial border of the suspensory ligament.

SUSPENSORY DESMITIS ASSOCIATED WITH AN EXOSTOSIS ON THE SECOND OR FOURTH METACARPAL OR METATARSAL BONE (SPLINT)

Suspensory desmitis associated with exostosis of the McII (MtII) or the McIV (MtIV) is discussed on page 419 (Figure 72-12).

SUSPENSORY DESMITIS ASSOCIATED WITH FRACTURE OF THE DISTAL THIRD OF THE SECOND OR FOURTH METACARPAL OR METATARSAL BONE

Suspensory desmitis associated with fracture of the distal third of the McII (MtII) or the McIV (MtIV) is discussed on page 421.

SUSPENSORY DESMITIS: BRANCH LESIONS

Desmitis of the medial and/or lateral branches of the SL in forelimbs and hindlimbs is a relatively common injury in all types of sports horses. Usually only a single branch is affected in a single limb, although both branches may be affected, especially in hindlimbs. Foot imbalance often is recognized in affected horses and may be a predisposing factor. Some horses, particularly event horses, have acute-onset distention of the metacarpophalangeal joint capsule concurrent with SL branch desmitis. Detection of

radiological abnormalities (modeling or fracture of the distal aspect of the McII or the McIV or a PSB) in some horses at the time of recognition of an acute, first-time injury suggests a subclinical preexisting problem. As with PSD, there is some evidence that some suspensory branch injuries in hindlimbs may be degenerative in origin.⁴⁸

Clinical Signs

The clinical signs depend on the degree of damage and chronicity of the lesion(s) and include localized heat and swelling. Swelling often is caused by enlargement of the branch, together with periligamentous edema or fibrosis. In some hindlimb injuries swelling may be predominantly because of periligamentous fibrosis. Associated distention of the metacarpophalangeal or metatarsophalangeal joint capsule may occur because of the subsynovial location of the axial aspect of the distal third of the ligament.⁴⁹ In hindlimbs sometimes considerable distention of the digital flexor tendon sheath (DFTS) occurs, making assessing the SL branches by palpation difficult. Mild swelling may also easily be overlooked unless a standardized method of palpation is used. A normal SL is uniform in dorsopalmar (dorsoplantar) width throughout its length. With the limb bearing full weight, place the thumbs of both hands on the dorsal and palmar (plantar) aspect of the SL body and follow the ligament distally. The thumbs should remain equidistant unless there is enlargement of the SL. The medial and lateral branches should both be assessed routinely. Pain usually is elicited by direct pressure applied to the injured branch or by passive flexion of the fetlock. Lameness varies, may be absent, usually is proportional to the degree of damage, and is related inversely to the duration of injury. A notable exception is in the hindlimbs of older dressage horses, in which occasionally both branches sustain damage, and strong adhesions develop between them. These horses experience persistent, severe lameness. Occasionally, younger horses from any discipline develop acute-onset, severe, and persistent hindlimb lameness associated with progressive stretching of a single branch and the development of periligamentous fibrosis. There is associated hyperextension of the fetlock.

Diagnosis

Diagnosis is based on clinical signs and ultrasonographic examination. Diagnostic analgesic techniques usually are required only if more than one lesion is suspected as the cause of lameness. In horses with acute branch injury with concurrent distention of the metacarpophalangeal joint capsule, we suggest that the horse be reevaluated after 2 to 3 weeks. If joint capsule distention and pain on manipulation persist, then the joint should be blocked intraarticularly.

The entire SL should be examined by ultrasonography, because lesions may extend beyond areas that are palpably abnormal. Ultrasonographic abnormalities include the following (Figures 72-13 to 72-15):

- Abnormalities of the body of the SL (see page 749)
- Enlargement of the branch
- Change in shape of the branch
- Loss of definition of one or more margins of the branch
- Well-defined or poorly defined hypoechoic areas, central or peripheral

Fig. 72-13 • A, Transverse ultrasonographic image of the medial branch of the suspensory ligament of the right forelimb of a 14-year-old Grand Prix dressage horse. The suspensory ligament branch is enlarged (cross-sectional area 2.02 cm²) and has a large, almost anechoic lesion. The echogenic material subcutaneously also contributed to the soft tissue swelling. **B,** Longitudinal ultrasonographic image of the medial branch of the suspensory ligament of the right forelimb of the same horse. Proximal is to the left. There is a marked loss of fiber pattern within the suspensory ligament. Note also the subcutaneous echogenic material.

- A diffuse reduction of echogenicity involving some or all of the cross-sectional area of the branch
- Echogenic material subcutaneously; this may be uniform in echogenicity or include areas of reduced echogenicity reflecting tearing of periligamentous fibrous tissue
- Echogenic material between the medial and lateral branches
- Hyperechogenic foci or larger masses within the branch
- An irregular contour or fracture of the ipsilateral PSB
- An abnormal amount of fluid within the DFTS and/or the metacarpophalangeal (metatarsophalangeal) joint

The branches should be examined in transverse and longitudinal planes. Lesions restricted to the insertion are sometimes detectable only in longitudinal images. Sometimes horses show slight localized swelling and heat

in the region of a SL branch, with a subtle alteration in gait, in which no ultrasonographic abnormality of the SL can be identified. The swelling appears to be principally periligamentous. Some of these horses can be maintained safely in work, whereas in others clinical signs deteriorate with the development of a branch lesion. Recurrent lameness may also result from tearing of periligamentous fibrous tissue. Occasionally, concurrent lesions of the oblique sesamoidean ligaments occur.

Radiological examination of the ipsilateral splint bone and PSB should be performed. Abnormalities may include the following:

- Dystrophic mineralization in the SL
- Distortion in shape of the ipsilateral splint bone
- Fracture of the distal aspect of the ipsilateral splint bone
- Fracture(s) of the ipsilateral PSB (see [Figure 72-15](#))
- Radiating lucent lines within the ipsilateral PSB
- Modeling of the palmar aspect of the PSB
- Abnormally distal location of the PSB, reflecting stretching of the SL

Fractures influence the treatment and prognosis. However, radiological evidence of sesamoiditis is not well correlated with the outcome, although primary sesamoiditis unassociated with SL desmitis can cause recurrent lameness (see Chapter 36). Occasionally lesions cannot be identified using ultrasonography but are recognized using MRI.

Management

Treatment depends on the occupation of the horse, the breed, and the severity of the clinical signs and ultrasonographic abnormalities. There are no large-scale, peer-reviewed reports of the success of management of SL branch injuries in either racehorses or sports horses. Horses with acute central core lesions may be treated by splitting (desmoplasty), with horses returning to work within 9 months. Horses with more peripheral or poorly demarcated lesions are not suitable for splitting, but their injuries can be managed conservatively by appropriate trimming and shoeing, box rest, and a controlled increasing exercise program. Intralesional injection of β -aminopropionitrile fumarate (five 7-mg injections on alternate days) combined with a controlled increasing work program over 6 to 9 months has been successful.³⁰ There are anecdotal reports of the success of mesenchymal stem cell treatment or intralesional injection of platelet-rich plasma or bone marrow. Our experience to date is that the results are rather unpredictable, although some excellent outcomes have been achieved.

Dressage horses and show jumpers with minor lesions and only subtle ultrasonographic abnormalities have been managed successfully by appropriate trimming and shoeing with egg bar shoes, combined with modification of the training program for 6 to 8 weeks. Some horses can be managed successfully and maintained in work by aggressive local therapy (e.g., use of whirlpool boots, laser or ultrasound therapy, leg sweats, and cold therapy). Continued work in an event horse usually results in substantial progression of the lesion. In a TB racehorse, continued training in the face of SL branch injury runs the risk of an acute breakdown injury of the suspensory apparatus. In STB racehorses symptomatic treatment is common, with NSAIDs as required, daily icing, topical application of a

Fig. 72-14 • A, Transverse ultrasonographic image of the lateral branch of the suspensory ligament of the left hindlimb of a 7-year-old intermediate-level event horse with lameness of 2 weeks' duration. The suspensory branch is considerably enlarged (cross-sectional area 2.0 cm²). Its margins are poorly defined, and there is marked loss of echogenicity. **B**, Longitudinal ultrasonographic image of the lateral branch of the suspensory ligament of the same horse. Proximal is to the left. The ligament is hypoechoic, with loss of fiber pattern.

Fig. 72-15 • A, Transverse ultrasonographic image of the lateral branch of the suspensory ligament, close to its insertion on the lateral proximal sesamoid bone, of the right hindlimb of a 9-year-old advanced event horse with acute-onset lameness. The ligament has a large, almost anechoic defect. **B**, Flexed, slightly oblique lateromedial radiographic image of the right hind fetlock of the same horse. The lateral proximal sesamoid bone is positioned slightly more dorsally. Several small osseous opacities are seen dorsal to it. These were removed arthroscopically, and torn fibers at the suspensory ligament branch insertion were debrided.

DMSO-cortisone liniment, and modification of the training schedule to light jogging or swimming between races. Lesions may remain stable or progress slowly and usually ultimately compromise performance substantially. Management is more difficult in horses that race at a high level, in which training cannot be reduced enough or the speed of the race results in overload of the compromised structure. Horses seem to do less well on a slower track surface, with a deep cushion, compared with a fast track surface.

Ultrasonographically, lesions are often slow to resolve and some persist long term (longer than 18 months). Some horses are able to resume full work after a convalescent

period of at least 9 months, despite the persistence of a lesion, although the incidence of recurrent injury is high. If a lesion persists as viewed by ultrasonography, knowing when to recommend resumption of work is difficult. Generally the horse should have been rested at least 6 months, and no appreciable change should be found in the ultrasonographic appearance of the SL branch between two examinations 3 months apart. With increased exercise the ligament should remain stable in size and echogenicity.

Arthroscopic examination of the palmar (plantar) pouch of the metacarpophalangeal (metatarsophalangeal) joint may be indicated if there is persistent synovial

distention associated with an axial lesion of the SL branch.⁴⁹ Intrasynovial torn fibers can be debrided and, occasionally, small avulsion fractures removed. Thirteen of 18 horses (72%) with an axial branch injury that involved the fetlock joint returned to full athletic function for between 5 months and 6 years.⁴⁹

Horses with forelimb or hindlimb suspensory branch lesions with periligamentous fibrosis, or echogenic material extending between the two branches (seen more often in hindlimbs) have a poor prognosis. This echogenic material represents firm fibrous adhesions between the branches. Periligamentous fibrosis impedes mobility of the SL branch and is often associated with a disproportionately severe lameness compared with lesions of the branch itself. There are anecdotal reports of surgical debridement, but the results have been disappointing. An abnormally low position of the PSBs is also a poor prognostic indicator, reflecting degeneration and stretching of the suspensory apparatus.

PROXIMAL SESAMOID BONE FRACTURE ASSOCIATED WITH A BRANCH INJURY

Proximal sesamoid fractures associated with SL branch injury are discussed on page 404.

AVULSION FRACTURE OF A PROXIMAL SESAMOID BONE AT THE INSERTION OF THE PALMAR ANNULAR LIGAMENT

Avulsion injuries of the palmar annular ligament (PAL) at its insertion on a PSB are not common^{29,50} and must be differentiated carefully from abaxial PSB fractures (see Chapter 36, page 405). Injuries occur in forelimbs and hindlimbs. Horses with acute injury show lameness associated with diffuse soft tissue swelling palmar to a PSB.²⁹ Swelling does not involve the ipsilateral SL branch unless that branch has been damaged concurrently. There may also be mild distention of the fetlock joint capsule and the DFTS. It may be possible to elicit pain by firm pressure applied to the abaxial aspect of the PSB. In horses with more chronic injury no localizing clinical signs may be apparent. Radiological examination may reveal a punched-out lesion of the PSB (Figure 72-16) or a small detached fragment of bone (Figure 72-17), the origin of which cannot be determined. Ultrasonographic examination helps to determine the origin of the fragment. The PAL should be examined from the palmar aspect of the limb and then followed around to its insertion. An osseous echogenic body may be seen attached to the PAL close to the PSB. Treatment by surgical removal of the fragment or conservative management has resulted in return to full athletic function.^{29,50}

DAMAGE OF THE PALMAR (PLANTAR) LIGAMENT OF THE FETLOCK (INTERSESAMOIDEAN LIGAMENT)

Focal Tears in the Body of the Intersesamoidean Ligament

Focal tears in the body of the intersesamoidean ligament are an unusual cause of lameness and can be diagnosed

Fig. 72-16 • Dorsolateral-palmaromedial oblique radiographic image of the right front fetlock of a 7-year-old advanced event horse. A punched-out radiopacity is visible on the palmar aspect of the bone (*arrow*). This is an avulsion injury at the insertion of the palmar annular ligament. Note also the new bone on the palmar distal aspect of the bone.

definitively only by arthroscopic evaluation of the palmar (plantar) pouch of the metacarpophalangeal (metatarsophalangeal) joint.²⁹ Lameness is usually acute in onset and moderate to severe. Lameness improves with rest but often persists. There may be effusion in the metacarpophalangeal (metatarsophalangeal) joint. Lameness is improved by intraarticular analgesia. Usually no identifiable radiological abnormalities occur. Small focal tears are extremely difficult to identify using ultrasonography. Nuclear scintigraphic examination of a small number of horses with small focal tears not involving the insertion of the ligament has revealed slight generalized IRU in the fetlock region but not localized to the PSBs. Horses with focal ligament tears have a poor response to surgical debridement and prolonged rest, with or without intraarticular medication, and the prognosis for return to athletic function is guarded.

Degeneration or Partial Rupture of the Intersesamoidean Ligament

Degenerative lesions and partial rupture of the intersesamoidean ligament have been seen only in older, mature athletic horses and are relatively rare.⁵¹ The condition has been recognized in forelimbs and hindlimbs and may occur as a single injury or with other soft tissue or bony lesions.

Lameness is acute in onset and moderate to severe. Mild distention of the metacarpophalangeal (metatarsophalangeal) joint capsule or the DFTS may occur. Lameness may be improved by intraarticular analgesia, but the response to perineural analgesia of the palmar (plantar) and palmar (plantar) metacarpal (metatarsal) nerves is often better.

Diagnosis is based on ultrasonography, and a number of abnormalities have been identified:

Fig. 72-17 • A, Dorsomedial-palmarolateral oblique radiographic image of the right front fetlock of a 9-year-old Grand Prix show jumper with acute-onset lameness associated with soft tissue swelling on the medial aspect of the fetlock, palmar to the medial branch of the suspensory ligament. There was also slight edematous swelling around the distal aspect of the medial branch of the suspensory ligament. There is an osseous fragment palmar to the proximal sesamoid bones, but its origin could not be determined radiologically. **B,** Transverse ultrasonographic image of the palmaromedial aspect of the fetlock. A thick hyperechoic line represents the osseous fragment (arrow) that was an avulsion of the insertion of the palmar annular ligament.

- An increase in the space between the PSBs
- An increased thickness of the palmar ligament
- Reduced echogenicity of the palmar ligament
- Focal hyperechogenic regions in the palmar ligament
- Dorsal displacement of the digital flexor tendons
- Thinning of the palmar ligament and reduction in the space between the ligament and the dorsal aspect of the DDFT
- Irregularity of the facies flexoria of a PSB (this may correlate with radiolucent areas in the axial aspect of the bone)

Careful examination of the digital flexor tendons, the PAL, and the distal sesamoidean ligaments should be performed to identify any concurrent injuries.

Radiological examination occasionally may reveal osteolytic lesions on the axial aspect of the PSBs (see the following discussion).

The prognosis for return to athletic function is extremely guarded.²⁹

Insertional Injury of the Intersesamoidean Ligament

Aseptic necrosis of the axial aspect of the PSBs has been described as a cause of lameness in forelimbs and hindlimbs.^{49,50} The condition has been characterized by the development of radiolucent zones in the axial aspect of one or both PSBs (Figure 72-18), lesions that have also been seen with infection (see the following discussion). Histological examination of two horses indicated that these lesions reflect trauma of the insertion of the intersesamoidean ligament.²⁹ Insertional lesions of the palmar ligament of the fetlock also may occur without radiological change and have been identified arthroscopically (Figure 72-19).

In contrast to horses with associated infection, usually no substantial soft tissue swelling occurs in the fetlock region, although distention of the metacarpophalangeal (metatarsophalangeal) joint capsule, the DFTS, or both may occur. In some horses, eliciting pain by palpation may be difficult. Lameness may vary from moderate to severe and is often worse with the horse walking in a circle compared with walking in a straight line.

Perineural analgesia by a four-point block usually results in much better improvement in lameness than intra-articular analgesia. In the acute stage radiological examination findings may be negative. Ultrasonographic evaluation may be unrewarding, but in some horses an irregular outline of one of the PSBs may be seen, with reduced echogenicity of the intersesamoidean ligament (see Figure 72-18).

Nuclear scintigraphic examination usually reveals focal, intense IRU in one or both PSBs, in contrast to the pattern of uptake that has been seen with focal lesions in the body of the intersesamoidean ligament (see the previous discussion). IRU localized to a PSB also may be caused by an incomplete fracture or subchondral trauma. Sequential radiological examination may reveal the development of lucent zones on the axial aspect of the proximal sesamoid bones.

These lesions may be associated with long-term lameness, although surgical debridement has resulted in return to former athletic function in some horses.^{52,53} Arthroscopic evaluation usually reveals a defect in the palmar ligament (see Figure 72-19), through which a probe can be inserted into the bony defect. Occasionally the palmar ligament is intact and must be incised to permit access to the osseous defect. Defects usually are more pronounced in one PSB, but they can involve both PSBs. Damaged palmar ligament and bone are debrided. Occasionally, to approach lesions not involving the articular surface, it may be necessary to create a small apical fracture to gain access to the bony defect.

INFECTION OF THE AXIAL ASPECT OF THE PROXIMAL SESAMOID BONES

Aseptic necrosis^{51,52} and osteomyelitis⁵⁴ of the PSBs have been described, but in one author's experience (SJD) aseptic necrosis occurs more commonly. *Aseptic necrosis* is probably an inappropriate term, because the Editors believe that lesions develop secondary to trauma of the insertion of the intersesamoidean ligament (see the previous discussion). Infection is not necessarily associated with a known route of infection, but several horses with infection have been

Fig. 72-18 • A, Dorsoplantar radiographic image of the right hind fetlock of a 6-year-old Thoroughbred with severe lameness associated with moderate distention of the metatarsophalangeal joint capsule and mild distention of the digital flexor tendon sheath. Medial is to the left. The axial borders of the proximal sesamoid bones are poorly defined proximally, with radiolucent areas in the bone (*arrows*). Histological examination confirmed traumatic insertional injuries of the palmar ligament of the fetlock. **B,** Transverse ultrasonographic image of the plantar aspect of the fetlock of the same horse. Medial is to the left. Note the irregularity of the outline of the proximal sesamoid bones and the rather heterogeneous echogenicity of the intersesamoidean ligament.

Fig. 72-19 • Arthroscopic picture of focal tear in the palmar ligament of the fetlock at its insertion on the medial proximal sesamoid bone. (Courtesy I.M. Wright, Newmarket, Suffolk, England.)

seen after puncture wounds in the pastern region or cellulitis²⁹ (Figure 72-20).

Infection of the PSBs may occur in forelimbs and hindlimbs and is characterized by radiolucent zones involving the axial margin of the medial or lateral PSB, or both. Pain may be elicited by pressure over the PSBs. Fetlock flexion usually is resented. Distention of the fetlock joint

capsule and the DFTS and surrounding soft tissue swelling are variable features. Synoviocentesis may reveal evidence of infection in adjacent structures. In some horses a penetrating wound can be identified in the palmar aspect of the fetlock or pastern. Lameness varies from moderate to severe.

High-resolution dorsal 15- to 20-degree proximal-palmarodistal (plantarodistal) oblique radiographic images, with adequate penetration, are essential for diagnosis. If the radiographs are underexposed, lesions will be missed. Ultrasonography is useful for confirming the diagnosis and for identifying other concurrent lesions (see Figure 72-20), such as extensive tenosynovitis of the DFTS, deposition of echogenic material around the affected PSB, reduced echogenicity of the intersesamoidean ligament, and lesions of the digital flexor tendons or adhesions between them.¹

The prognosis with conservative or surgical management is extremely guarded.

STRAIGHT SESAMOIDEAN DESMITIS

Desmitis of the straight sesamoidean ligament is an unusual cause of lameness that usually occurs in a forelimb, but it has been recognized in hindlimbs.⁵⁵⁻⁵⁸ One of the authors (SJD) has recognized it most commonly in event horses and show jumpers. The condition may occur alone, or together with injury to either an oblique sesamoidean ligament or other soft tissue lesions in the digit. Lameness is sudden in onset, usually with no detectable swelling in the acute phase. Some swelling may develop subsequently, but this can be difficult to detect if the lesion is far proximal. Concurrent effusion may occur in the DFTS, and palpation

Fig. 72-20 • **A**, Dorsopalmar radiographic image of the right metacarpophalangeal joint of an 8-year-old Thoroughbred with massive swelling of the metacarpal region, restricted flexibility of the fetlock, and distention of the digital flexor tendon sheath. There are large radiolucent zones involving the distal axial borders of the proximal sesamoid bones. **B**, Transverse ultrasonographic image of the distal aspect of the metacarpal region of the same horse. Note the asymmetrical appearance of the proximal sesamoid bones and the difference in distance between them and the dorsal border of the deep digital flexor tendon (DDFT). **C**, Transverse ultrasonographic image of the distal metacarpal region of the same horse. Note the abnormal amount of fluid within the digital flexor tendon sheath and the echogenic material around the DDFT. **D**, Palmar oblique ultrasonographic image. Note the subcutaneous echogenic material and the distended vessels. These lesions were associated with infection.

on the palmar midline of the pastern region may elicit pain, but not invariably so. Lameness may be severe acutely and then rapidly improving but persisting. Lameness is alleviated by palmar nerve blocks at the level of the base of the PSBs. Diagnosis is based on ultrasonography or MRI. Ultrasonographic abnormalities include the following (Figure 72-21):

- Enlargement of the straight sesamoidean ligament and therefore reduction in the space between it and the DDFT

- Focal or diffuse reduction in echogenicity
- Increased fluid within the DFTS in some horses

Care should be taken not to misinterpret the normal hypoechoic area in the most distal part of the ligament as a lesion. This represents the cartilaginous scutum at the insertion.

Lesions may occur localized to the insertion, either unilaterally or bilaterally, and alone or in conjunction with other causes of palmar foot pain, such as navicular disease.

Fig. 72-21 • Transverse ultrasonographic images of the left (on the left) and right proximal pastern regions of an advanced event horse with acute-onset, severe right forelimb lameness after completion of a cross-country course. The lameness improved greatly within 24 hours. Flexion of the right front fetlock elicited pain, but no swelling or pain on direct palpation could be detected. Lameness was alleviated by perineural analgesia of the palmar nerves at the level of the fetlock joint. The right straight sesamoidean ligament is enlarged (cross-sectional area 1.46 cm²) compared with the left (1.35 cm²), resulting in loss of space between it and the deep digital flexor tendon. The ligament is also hypoechoic.

There is often no palpable abnormality unless the injury is severe. Lameness is removed by perineural analgesia of the palmar nerves at the base of the PSBs. However, improvement may be seen after palmar digital nerve blocks if these are performed in the midpastern region or because of proximal diffusion from a more distal injection site. Although some lesions can be identified ultrasonographically, the shape of the pastern influences the ease with which these structures can be imaged accurately. Recent experience with MRI suggests that these injuries may occur more frequently than previously recognized. MRI seems more sensitive than ultrasonography for the detection of these injuries.^{58,57} Improvement in lameness may also be seen after intrathecal analgesia of the DFTS, presumably because of local diffusion of local anesthetic solution.

Occasionally, concurrent lesions of the straight and oblique sesamoidean ligaments occur and have a more guarded prognosis.

Treatment has consisted of box rest, corrective trimming and shoeing, and controlled walking exercise, with periodic reevaluation with ultrasonography. Intralesional injections of bone marrow, platelet-rich plasma, or mesenchymal stem cells could be considered, although limited experience to date has not yielded good results. Usually, progressive resolution of lameness occurs over 6 to 8 weeks, with gradual improvement in the ultrasonographic appearance of the ligament over 6 months. However, the prognosis for return to full athletic function at a high level of competition is guarded because the incidence of recurrent injury is high. Severe lesions have shown poor capacity to heal, with persistent lameness.

Loss of tension (relaxation) of the straight sesamoidean ligament may occur if the SL is ruptured, resulting in instability or luxation of the proximal interphalangeal joint (palmar or plantar subluxation). Ultrasonographic abnormalities include the following:

- Apparent enlargement of the ligament cross-sectional area
- Loss of fiber alignment
- Focal hypoechoic areas caused by lack of tension

OBLIQUE (MIDDLE) SESAMOIDEAN DESMITIS

Desmitis of one or both oblique sesamoidean ligament(s) occurs in forelimbs and hindlimbs, but it is a more common source of forelimb lameness. Lameness is usually acute in onset and moderate to severe. In the acute stage often no localizing clinical signs are apparent, but in the following 7 to 10 days swelling may develop in the pastern region, and pain may be elicited by firm palpation. However, lesions may occur without detectable palpable abnormalities, alone or with another cause of lameness. Severe lesions may be associated with dorsal subluxation of the proximal interphalangeal joint, characterized clinically by an abnormal convex contour on the dorsal aspect of the pastern at the level of the joint. With chronic lesions dorsal extension of the joint margins of the proximal interphalangeal joint may be seen radiologically. Lameness, which is often worst on a soft surface, is usually alleviated by palmar (abaxial sesamoid) nerve blocks. One should note that tendonitis of the medial or lateral branch of the SDFT is a more common injury in the pastern, has a similar clinical presentation, and is more likely to be associated with detectable soft tissue swelling. Lesions of an oblique sesamoidean ligament may be localized to the origin immediately distal to the PSB, and pain associated with such lesions may be abolished by intraarticular analgesia of the fetlock joint, reflecting the close anatomical relationship between the palmar (plantar) distal outpouchings of the fetlock joint capsule. Intrathecal analgesia of the DFTS may also result in resolution of lameness, presumably because of local diffusion of local anesthetic solution.

Fig. 72-22 • **A**, Transverse ultrasonographic image of a 7-year-old Thoroughbred with left forelimb lameness of 10 days' duration. Medial is to the left. The lateral oblique sesamoidean ligament is diffusely hypoechoic (arrow). **B**, Transverse ultrasonographic image of a 12-year-old Warmblood with left hindlimb lameness of 6 days' duration obtained immediately distal to the lateral proximal sesamoid bone. The oblique sesamoidean ligament is enlarged and diffusely hypoechoic (arrows).

One also must recognize that enthesophyte formation on the palmar aspect of the proximal phalanx at the site of insertion of the oblique sesamoidean ligaments is a common incidental radiological abnormality frequently unassociated with clinical signs and often is not associated with any detectable ultrasonographic structural abnormality of the ligament. Well-circumscribed, smoothly marginated osseous bodies, possibly old avulsion fractures from the base of a PSB, are common radiological and ultrasonographic observations in mature horses in which the oblique sesamoidean ligament appears to be structurally normal.

Ultrasonographic abnormalities of the oblique sesamoidean ligament are often identified concurrently with some other cause of lameness—for example, osteoarthritis of the proximal interphalangeal joint or desmitis of a branch of the SL.

Ultrasonographic abnormalities include one or more of the following (Figures 72-22 and 72-23):

- Enlargement
- Diffuse reduction of echogenicity
- Focal hypoechoic areas
- Poor demarcation of the margins of the ligament
- Reduction in space between the ligament and the SDFT
- Enthesophyte formation on the palmar (plantar) aspect of the proximal phalanx or the base of the ipsilateral PSB
- An avulsion fracture of the base of the ipsilateral PSB or at the insertion on the palmar aspect of the proximal phalanx

Each ligament should be evaluated carefully in transverse and longitudinal planes. Occasionally lesions occur together with injuries to other soft tissues of the pastern, so all structures should be evaluated systematically. Some lesions are not detectable with ultrasonography but are identified using MRI.^{57,58}

Fig. 72-23 • Longitudinal ultrasonographic image of the right front pastern of a 7-year-old pleasure riding horse with moderate lameness. Proximal is to the left. A large enthesophyte (arrow) is visible on the palmar aspect of the proximal phalanx. The region of insertion of the oblique sesamoidean ligament is reduced markedly in echogenicity. The horse also had osteoarthritis of the proximal interphalangeal joint.

Horses with a primary injury of the distal sesamoidean ligaments have a high incidence of recurrent injury if returned to full athletic function after conservative management. The effects of surgical splitting or of biological agents such as platelet-rich plasma or mesenchymal stem cells remain unproven. However, horses with primary lameness from another cause may have an enlarged oblique sesamoidean ligament of normal echogenicity, apparently unassociated with clinical signs.

Fig. 72-24 • A, The hindlimbs of a 14-year-old Thoroughbred gelding with hyperextension of the hind fetlocks and soft tissue enlargement around the distal aspect of the branches of the suspensory ligaments. The superficial digital flexor tendon of the right hindlimb was subluxated laterally. **B,** The distal aspect of the suspensory ligament branches of the same horse. Considerable fibrous tissue surrounds the branches. The ligaments were discolored substantially, with no normal-appearing ligamentous tissue.

PROGRESSIVE ATRAUMATIC BREAKDOWN OF THE SUSPENSORY LIGAMENTS

Progressive degenerative changes in hindlimb SLs have been seen in a small number of horses that originally

showed PSD and had straight hock conformation. These horses developed hyperextension of the hind fetlock joints (Figure 72-24). The condition has been characterized by a diffuse decrease in echogenicity of the proximal aspect of the SLs, which becomes progressively more extensive distally. A similar clinical condition has been recognized in older horses, especially broodmares, with progressive hyperextension (dorsiflexion) of the hind fetlock joints, which may result in abrasion of the plantar aspect of the fetlocks. Progressive hyperextension of the hind fetlock joints also has been seen in middle-aged performance horses with apparent lengthening of branches of the SL and periligamentous fibrous reaction. Some breeds, including the Peruvian Paso⁵⁹⁻⁶¹ and Andalusian horses, seem particularly at risk and may show evidence of the condition in all four limbs. The condition is generally bilateral and is usually associated with a deterioration in hindlimb gait rather than an overt lameness, although Peruvian Pasos may be more severely affected. Secondary lateral luxation of the SDFT from the point of hock occurs occasionally, probably associated with the straight angle of the hock.

Histologically the lesions are characterized by chondroid metaplasia, associated proteoglycan deposition, and acellular and fibrillated collagen fibers and merger of adjacent fascicles of fibrillated collagen to form megafascicles. Granulation tissue in interfascicular septae makes abortive attempts at repair.

The cause of these conditions is not known. They are probably complex disorders involving genetic, molecular, conformational, and biomechanical factors. It has been suggested that in the Peruvian Paso the condition is associated with a systemic disorder characterized by proteoglycan accumulation⁶¹; however, this conclusion has been refuted.⁶² The SLs and other tissues from affected Peruvian Pasos and unaffected STBs and Quarter Horses were examined using Safranin-O staining for detection of proteoglycan. Proteoglycan deposition was not unique to the affected Peruvian Pasos, being present in the nuchal ligament, heart, muscle, and other tissues, with similar or greater amounts in the control horses. However, greater amounts were detected in the SLs of affected horses compared with control horses. It was concluded that cartilage metaplasia and associated proteoglycan deposition in affected SLs were the response to injury rather than the cause.

The condition is generally progressive. Flat shoes with plantar extensions help to lift the fetlock and may prevent secondary trauma, but the prognosis for proper athletic function is guarded.

TRAUMATIC DISRUPTION OF THE SUSPENSORY APPARATUS

Traumatic disruption of the suspensory apparatus is discussed on page 969.

Clinical Use of Stem Cells, Marrow Components, and Other Growth Factors

Scar tissue that forms after tendon and ligament injuries is architecturally and biomechanically inferior to normal tissues, rendering the structure susceptible to reinjury.¹ The goals of regenerative therapies, such as stem cells and growth factors, are to restore normal structure and function to tissues to enhance healing, restore pain-free physical activity, and avoid reinjury. Successful regenerative healing of any tissue is intended to closely mimic events of development in which there are spatial and temporal interactions between scaffold, growth factors, and cell populations. An understanding of the molecular and mechanical processes involved in the development of tendon and ligamentous injuries and between acute and repetitive overload pathologies will help guide development of target therapies for each specific disorder.

For many of the regenerative therapies presently available, technology and marketing are ahead of laboratory and clinical research. Most of the products being used to manage equine tendon and ligament injuries have been evaluated experimentally to some extent, but long-term clinical safety and efficacy data are limited. Ideally, the efficacy data would be obtained using prospective, blinded, and controlled clinical trials, although these studies are exceedingly difficult and expensive to perform. At a minimum, results of new treatments should be compared retrospectively with carefully selected historical case-matched studies. As part of a comprehensive plan, benefits from adjunctive surgical manipulations should also be evaluated. Desmotomy of the accessory ligament (superior [proximal] check ligament) of the superficial digital flexor tendon (SDFT) should be considered for horses with superficial digital flexor (SDF) tenosynovitis. In areas where a tendon or ligament is anatomically confined by surrounding structures and therefore susceptible to compression, such as the fetlock canal and carpal canal for horses with tendon injuries, as well as the proximal metacarpal/metatarsal regions in horses with enlargement of the proximal aspect of the suspensory ligament, surgical release of the restricting fascia should be implemented as part of a multitargeted approach to tendon/ligament healing. Critical to a successful outcome of all treatment regimens is a carefully implemented rehabilitation program. Well documented in studies of regenerative healing is the importance of mechanical stimulation and the type and quantity of the scaffold, growth factor(s), and/or stem cells.²⁻⁶

STEM CELL THERAPIES

The therapeutic role of stem cells in regenerative medicine is not fully understood. It is unclear whether stem cells ultimately function as a tissue-specific cell, such as a tenocyte, or whether they primarily improve tissue repair through secretion of immunomodulatory and trophic bioactive factors.⁷ These questions are not purely pedantic in nature because if stem cells are truly immunomodulatory, then allogeneic transplantations should be possible. If allogeneic stem cells were efficacious and could be used safely, then “off-the-shelf” stem cell products could be developed to increase availability and rapid implementation of stem cell therapies.

The stem cell field continues to rapidly evolve experimentally and clinically. At a basic level, stem cells are broadly defined as undifferentiated cells that possess the ability to divide for indefinite periods in culture and may give rise to highly specialized cells of each tissue type (i.e., mesoderm, ectoderm, and endoderm). There are two broad categories of stem cells: embryonic and adult derived (see Hipp and Atala⁶ and Tweedell⁸ for recent reviews). Embryonic stem (ES) cells used to be defined as those derived from embryos, more specifically from day 8, preimplantation blastocysts. Using recent advances, ES cells can be generated from adult fibroblasts using many of the same technologies that were used to clone Dolly the sheep. These cells are known as induced pluripotent stem (iPS) cells. Adult-derived mesenchymal stem cells (MSCs) can be obtained from bone marrow, fat, umbilical cord blood, muscle, and many other tissues, including cartilage, trabecular bone, and tendon.⁶ Hematopoietic stem cells (HSCs) are those cells in bone marrow, which are the basis of bone marrow transplantation, and are capable of forming all types of blood cells. Arguments can be made about the optimal source of stem cells for regenerative therapy; importantly, studies are needed to define the need for stem cells in such endeavors. Presently, stem cell therapies for tendon or ligament regeneration in horses are not regulated by the Food and Drug Administration in the United States or elsewhere.⁹

Commonly Used Stem Cell Products

Presently, there are three approaches to using stem cell therapy in horses, and all use MSCs, although equine ES, iPS, and umbilical cord blood-derived cells are beginning to be investigated. First, MSCs in a mixed cell population can be harvested from bone marrow aspirates; second, MSCs from bone marrow can be cultured; and third, a mixed cell population of MSCs can be harvested from adipose tissue. Each technique has its strengths and weaknesses.

Bone Marrow–Derived MSCs (BM-MSCs)

BM-MSCs can be easily and noninvasively obtained and compared with other MSCs, and they have a greater capacity to differentiate into other tissue types.¹⁰⁻¹² BM-MSCs have received the most scientific attention and hence are the best characterized. The process is straightforward. In standing sedated horses, bone marrow is collected from the sternum or the tuber coxae using local analgesia. Fresh bone marrow is either injected directly into the injured

tissue, or the nucleated adherent cell population (containing the BM-MSCs) is isolated and expanded in the laboratory before injection.

Bone Marrow Aspirate and Injection of Fresh Bone Marrow

Bone marrow is aspirated from the sternum at a site where the cranial third of the girth would sit (Figure 73-1). This site is relatively safe and has large marrow spaces compared with the marrow spaces cranial and caudal to the girth. However, it must be borne in mind that several horses have died as a result of inadvertent puncture of the heart during bone marrow collection from the sternum. The horse has seven sternal marrow spaces, and they become progressively smaller toward the manubrium and xiphoid processes (Figure 73-2). Ultrasonography is used by some to locate the sternabrae to avoid inadvertent penetration of the intersternbral space and puncture of the heart. The site is clipped, surgically prepared, and a bleb of local anesthetic solution is injected subcutaneously over the aspiration site(s). Bone penetration and aspiration are facilitated by use of a bone marrow (Jamshidi) biopsy needle with a double-diamond stylet and interlocking T-handle, with a large inner diameter cannula (e.g., 11 gauge \times 100 mm). Ideally, the site of injection in the tendon/ligament is aseptically prepared before obtaining the bone marrow aspirate, so that the bone marrow can be injected under ultrasonographic guidance immediately to avoid clotting in the syringe. If performed efficiently, anticoagulant is not necessary, which further simplifies the direct aspiration-injection technique. Advantages of this approach are the simplicity of the technique, ability to perform the procedure at the time of diagnosis, and the relatively low cost. The primary disadvantage is the low number of stem cells that are contained in raw bone marrow aspirates. In people and cats, the number of stem cells in raw bone marrow is

reported to be 0.001% to 0.01% of the mononuclear cell population.^{13,14} Using the direct aspiration-injection technique, Herthel¹⁵ reported improved clinical outcome in horses affected with suspensory desmitis.

Culture-Expanded BM-MSCs

There is experimental evidence to support the use of isolated and culture-expanded BM-MSCs from investigations in laboratory animals, in which MSCs were implanted into surgically created lesions. Improvement in tissue organization and composition and mechanics compared with controls was seen after injection of MSCs into tendons and ligaments.¹⁶⁻¹⁸ To obtain 10×10^6 cells, the recommended number for injection, approximately 3 weeks of culture is required to expand the selected cells. Implantation is performed as described using ultrasonographic guidance. After culture, the MSCs are suspended in the horse's own bone marrow supernatant or plasma to avoid injection of allogeneic antigens and to gain potential beneficial effects of rich growth factors that could be present in the supernatant. Laboratory research has demonstrated significant anabolic effects of bone marrow supernatant on tendon- and ligament-derived cells.¹⁹⁻²²

In a small case-control study ($n = 11$), BM-MSCs resulted in less reinjury of the SDFT in racehorses compared with a control population.²³ Recently, in more than 1000 horses treated with cultured BM-MSCs, Smith²⁴ found a significant decrease in reinjury rate for racehorses and other sports horses of all disciplines combined compared with conventionally treated historical controls. Ectopic bone formation, a potential problem when reimplanting BM-MSCs, was not observed in either study. Interestingly, Smith²⁴ reported that early (<44 days from injury) implantation of cells was associated with significantly less reinjury compared with those horses in which a longer interval between injury and implantation was used. These results suggest that implantation of cells before fibrous tissue formation enhances healing.

Fig. 73-1 • To obtain a sternal bone marrow aspirate, the bone marrow biopsy needle is inserted at the cranial extent of where a girth would cross the ventral aspect of the chest. Using this location, the needle would most likely enter the third sternal bone marrow space (see Figure 73-2).

Fig. 73-2 • Sagittal section of a sternum from a 450-kg adult horse (cranial is to the right) showing the typical six marrow spaces of the equine sternum. The needle shown in Figure 73-1 most likely enters the third marrow space. This marrow space is approximately 5 cm in diameter, and there it is approximately 5 cm from the ventral aspect of the sternum to the center of the sternal space. This picture demonstrates the diminishing amount of sternal cartilage surrounding the caudal sternal spaces. Although less ventral cartilage might facilitate entry into the marrow space, there is also less room for error dorsally and thereby increased risk of inadvertent cardiac puncture if the bone marrow aspirate needle is inserted too deeply. A generally safe guideline is to insert the bone marrow aspirate needle 2 to 3 cm after initial contact with the ventral aspect of the sternal cartilage. If no bone marrow aspirate is obtained, it is safest to move 2 to 3 cm cranial or caudal on the sternum and reattempt bone marrow aspiration.

There are several commercial and private laboratories providing services for isolation and expansion of BM-MSCs. Each laboratory has distinct directions for aspiration and shipping of bone marrow aspirate to the facility and for implantation of the resultant stem cell product. Therefore the chosen laboratory should be contacted directly for specific instructions.

Adipose-Derived MSCs (A-MSCs)

The currently available technique uses a mixed population of cells derived from adipose tissue surgically excised from the tail head region. The A-MSCs are not cultured but are simply isolated and reinjected into the horse. Compared with techniques using cultured BM-MSCs, this technique supplies a greater number of nucleated cells (not necessarily stem cells) in a short period (48 hours). The cells are reimplanted under ultrasonographic guidance. There are currently no published results for the application of A-MSCs in equine tendonitis, although the results of an experimental pilot study demonstrated significant improvement in histologic score in the A-MSC-treated tendons over phosphate-buffered saline-treated control tendons.²⁵ Like culture-expanded MSCs, the laboratory chosen to provide the service should be contacted for detailed instructions.

The Future of Stem Cell Therapy

There are several avenues of stem cell therapy for tendon or ligament injuries presently under investigation. Equine ES cells, umbilical cord blood-derived stem cells, and tendon-derived stem cells are in use for treatment of tendonitis or desmitis. Equine iPS cells are being investigated. iPS cells could have greater differentiation capacity than other adult-derived stem cells, and iPS cells are "horse specific," which will alleviate concerns of immune rejection. Finally, genetically modified stem cells have been investigated in vitro and in vivo and show tremendous promise for enhancing organized repair of tendons and other musculoskeletal tissues.²⁶

GROWTH FACTOR-BASED BIOLOGICS

Several medical treatments for equine tendonitis and desmitis have centered on delivery of single or multiple growth factors to the site of injury. Growth factors are protein signaling molecules that regulate cellular metabolism. They are temporally and spatially expressed during tendon and ligament development and repair.²⁷⁻²⁹ Growth factors stimulate cell proliferation, increase extracellular matrix synthesis, and promote vascular in-growth. In addition to the anabolic effects, growth factors down-regulate catabolic, matrix-degrading cytokines such as interleukins and matrix metalloproteinases.

The growth factors most widely studied in tendon and ligament healing include insulin-like growth factor-1 (IGF-1), platelet-derived growth factor (PDGF), bone morphogenetic protein-12, transforming growth factor- β (TGF- β), vascular endothelial growth factor (VEGF), growth/differentiation factor, and basic fibroblast growth factor.^{17,30-35} Growth factors are available individually as recombinant, purified proteins or can be injected within a less-defined milieu of a bone marrow aspirate or as platelet-rich plasma (PRP). Growth factors are delivered to a tendon or ligament using a series of intralesional injections. In the future, gene

therapy techniques could be used to deliver more sustained levels of growth factor expression.⁷ There are numerous animal studies demonstrating the advantages of using growth factors for enhanced healing of tendonitis, desmitis, and tendon lacerations, but despite these experimental studies, there are few long-term, multicentered, human or equine clinical data available for any of the growth factors. For example, experimentally, intralesional administration of IGF-1 enhanced return of tendon fiber pattern and improved mechanical characteristics in a collagenase-induced SDF tendonitis model.³⁴ Clinically, results after IGF-1 injection only appear comparable with those previously reported for flat-track racehorses treated with conservative therapy alone.

Platelet-Rich Plasma (PRP)

PRP is a fraction of venous blood with a concentrated platelet count, generally greater than two to four times normal baseline. During wound healing, platelet aggregation results in release of bioactive substances that promote tissue repair, regulate inflammation, and stimulate recruitment of stem cells.³⁶ Use of PRP in tissue healing is aimed at enhancing the natural biological process induced after platelet aggregation and degranulation. Platelets contain high concentrations of several growth factors, including PDGF, TGF- β , and VEGF, all of which have been shown using in vitro and in vivo animal models to enhance tendon and ligament healing.^{3,19,37-39} PRP is generated through a simple centrifugation or filtration process of venous blood to concentrate platelets. The advantages of using PRP include ease of use, administration of autologous peptides, delivery of a combination of growth factors, and low cost (relative to stem cells). After contact of platelets with exposed basement membrane in damaged soft tissues, PRP clots, resulting in the formation of a fibrin scaffold to allow for cellular migration into the injury, and as a mechanism to retain the growth factors at the site of injury. The primary disadvantages are the lack of stem cells within a preparation and the variability between the various products with respect to platelet concentration and residual leukocyte content.

Several companies are marketing specialized devices designed to create PRP. Not surprisingly, when investigated, platelet concentrations are highly and positively correlated to growth factor concentrations.³⁸ In addition, platelet concentrations are highly and positively correlated to tendon and ligament matrix gene expression. In other words, when platelet concentrations are high, there are more growth factors, as well as more extracellular matrix expression, such as collagen type I and cartilage oligomeric matrix protein, in both tendon and suspensory ligament. In contrast, white blood cell concentration is highly and positively correlated with collagen type III, which represents scar tissue, and with matrix-degrading enzyme gene expression. Collectively, these data support the notion of selecting a device with high platelet and low leukocyte concentration to maximize tissue repair and minimize further matrix loss.

Clinical evidence for the benefit of injecting PRP in people is encouraging.⁴⁰ In horses, a case-control study in Standardbred racehorses with midbody suspensory desmitis demonstrated that a single injection of PRP resulted in an excellent prognosis for return to racing (the Editors note that the prognosis associated with the return to racing of

Standardbred racehorses with suspensory desmitis is considered favorable with rest alone).⁴¹ Typically, PRP is injected into the affected tissue 7 to 10 days after injury when the inflammatory phase of wound healing is receding. The optimal number of platelets and frequency of injection have not been determined. A typical treatment protocol presently includes a single injection under ultrasonographic guidance using enough PRP to fill the defect

as observed ultrasonographically. Horses are reassessed every 30 days, and if substantial improvement in clinical and ultrasonographic findings is not observed, then a second injection should be considered. The majority of horses only require one injection. As with all other therapies, a controlled rehabilitation regimen is critical for successful repair, restoration of pain-free function, and prevention of reinjury.

Chapter 74

Diseases of the Digital Flexor Tendon Sheath, Palmar Annular Ligament, and Digital Annular Ligaments

Michael C. Schramme and Roger K.W. Smith

Synovial effusion of the digital flexor tendon sheath (DFTS) is common in all types of working horses. Frequently, effusion is idiopathic in origin and affects the DFTS of both hindlimbs without causing lameness. Occasionally synovial effusion is seen in a single limb along with lameness. Before the advent of ultrasonography and tenoscopy, injury to the soft tissue structures of the DFTS often remained unrecognized. The cause of chronic synovial effusion and lameness remained elusive, and a diagnosis of idiopathic tenosynovitis was made readily. Because modern diagnostic techniques have become commonplace in equine lameness practice, specific injuries of the structures of the DFTS have been identified.

ANATOMICAL CONSIDERATIONS

The detailed anatomy of the DFTS and its contents was well described¹ and is similar in forelimbs and hindlimbs. Reference is made to palmar and metacarpal region throughout, but the terms *plantar region* and *metatarsal region* strictly apply to the hindlimb. The DFTS is a thin-walled structure that encompasses the superficial digital flexor tendon (SDFT) and the deep digital flexor tendon (DDFT) from the level of the distal third of the metacarpal region to the T ligament, just proximal to the navicular bursa and the palmar pouch of the distal interphalangeal joint. The DFTS is mesenchymal in cell origin and is composed of two layers: an outer fibrous layer and an inner synovial layer. The fibrous layer provides strength and vascularity to the sheath. The synovial layer provides a smooth, frictionless surface and produces constituents of the synovial fluid. The palmar wall of the sheath incorporates three annular

ligaments: the palmar annular ligament (PAL) and the proximal and the distal digital annular ligaments. These annular ligaments bind the digital flexor tendons to the palmar aspect of the digit, are effectively thickenings of the fibrous layer of the sheath wall with a transverse fiber orientation, and measure 2 mm or less in thickness.

The PAL or annular ligament of the fetlock joint inserts on the palmar border of the proximal sesamoid bones (PSBs), is continuous with the palmar (intersesamoidean) ligament of the fetlock joint, and thus converts the proximal scutum into an inelastic canal. The strong, transversely arranged fibers of the PAL bind down the digital flexor tendons into the proximal scutum. Distal to the PAL and immediately under the skin, the deep fascia forms a second, quadrilateral ligament: the proximal digital annular ligament. This ligament is a fibrous sheet that covers and adheres to the palmar surface of the SDFT and attaches laterally and medially by two bands to the proximal phalanx: one to the proximopalmar tuberosity and one that joins the insertion of the distal branch of the SDFT to the distal part of the proximal phalanx. This arrangement firmly binds the SDFT and DDFT, enveloped by the DFTS, in the palmar pastern region. The distal digital annular ligament adheres to the palmar surface of the distal part of the DDFT and binds down the terminal part of this tendon. The ligament is a crescent-shaped fibrous sheet attached by a strong band on either side of the middle of the proximal phalanx, covering the distal branches of the SDFT.

The dorsal wall of the DFTS is formed by the proximal scutum, middle scutum, and distal sesamoidean ligaments. The proximal scutum and the middle scutum are strong fibrocartilaginous pads that allow sliding of the digital flexor tendons along the palmar aspect of the fetlock and pastern regions, respectively. The proximal scutum is composed of the two PSBs and the thick intersesamoidean ligament. The latter is a thick sagittal structure made of transversely aligned collagen fibers. The intersesamoidean ligament covers and is attached strongly to the whole palmar and axial aspect of the PSBs and creates a solid union between these bones. The concave palmar face of the proximal scutum allows sliding of the digital flexor tendons in the palmar fetlock region. The proximal scutum extends proximally to the apex of each PSB between the two distal branches of the suspensory ligament (SL). Distally the proximal scutum gives origin to the distal sesamoidean ligaments, which represent the functional continuation of the SL and consist of the straight, oblique, cruciate, and short sesamoidean ligaments. The straight sesamoidean ligament inserts distally on the middle scutum, together with the distal branches of the SDFT and the palmar ligaments of

the proximal interphalangeal joint. The middle scutum is a thick, fibrocartilaginous structure attached to the proximal palmar aspect of the middle phalanx. The middle scutum contacts the palmar aspect of the distal condyles of the proximal phalanx dorsally and the DDFT palmarly.

Within the DFTS, the SDFT and DDFT are intimately related. A fibrous ring (the manica flexoria) emanates from the lateral and medial borders of the SDFT and encircles the DDFT completely, from the proximal limit of the DFTS to the proximal aspect of the PSBs. The synovial lining of the DFTS adheres to the palmar surface of the SDFT in the sagittal midline proximal to the PAL, along the dorsal surface of the PAL and along the dorsal surface of the proximal digital annular ligament. The synovial lining of the DFTS also adheres to the palmar surface of the DDFT between the proximal digital annular ligament and the distal digital annular ligament, and along the dorsal surface of the distal digital annular ligament. The sagittal adhesion-like mesotendon between the SDFT and PAL is referred to as the vinculum of the SDFT. The DDFT also has a mesotendon that attaches to its palmar surface at the level of the proximal interphalangeal joint (see Figure 70-2, B). These mesotendon attachments contain vascular branches that contribute to the arterial supply of the intrasynovial part of the tendon.

The DFTS facilitates displacement of the digital flexor tendons during flexion and extension of the fetlock and interphalangeal joints. During metacarpophalangeal (metatarsophalangeal) joint movements, the two digital flexor tendons displace together, but during interphalangeal joint movements, displacement of the DDFT is greater than that of the SDFT.

DIAGNOSTIC TECHNIQUES

Diagnostic techniques that localize disease to the DFTS include synoviocentesis and synovial fluid analysis and intrathecal or perineural injection of local anesthetic solution. Synoviocentesis of the DFTS can be performed in one of the several recesses of the sheath. Access to the proximal pouch is possible when the sheath is distended with synovial fluid but difficult when it is not. Synoviocentesis can be achieved by introducing a 2.5-cm needle along the dorsal aspect of the DDFT, between the DDFT and the lateral branch of the SL, a few centimeters proximal to the lateral PSB. Easier access can be gained via the distal palmar pouch of the sheath, which extends between the two distal branches of the SDFT and between the two digital annular ligaments, along the palmar surface of the DDFT. One should remember that this pouch is divided sagittally by the mesotendon of the DDFT in its distal part. The needle can be introduced through the skin to one side of the midline and, to avoid iatrogenic damage to the DDFT, gently and slowly advanced at approximately 45 degrees to the skin surface until synovial fluid is seen at the needle hub. To increase distention of the distal palmar recess, it can be useful temporarily to compress the proximal pouch by firm application of an elasticated bandage (see Figure 124-1). Alternatively, the needle can be aimed to access this pouch between the lateral or medial border of the DDFT and the ipsilateral distal branch of the SDFT, which will prevent inadvertent needle penetration of the DDFT, although the palmar pouch of the proximal interphalangeal joint can be entered if the needle is introduced too

deeply. The DFTS also can be accessed through its proximal or distal collateral recesses. The proximal collateral recess is situated in the triangular space palmaromedially or palmarolaterally, between the base of a PSB, the proximal insertion of the proximal digital annular ligament, and the dorsal border of the DDFT. The space can be entered 1 cm distal to the base of a PSB and 1 cm palmar or plantar to the neurovascular bundle. The distal collateral recess is located on the lateral (or medial) aspect of the pastern, between the digital flexor tendons and the distal sesamoid ligaments and between the proximal and distal insertions of the proximal digital annular ligament. A cadaver study showed that synoviocentesis of the DFTS using these techniques was most consistently successful when performed at the level of the proximal lateral recess on a non-weight-bearing limb.² In addition, a palmar-plantar axial sesamoid approach was described where the needle was introduced axial to the PSB in the flexed limb. This technique was described as being optimal for synoviocentesis.³ Ten milliliters of local anesthetic solution is injected for adequate analgesia of the DFTS (see Chapter 10). It is important to recognize that intrathecal analgesia of the DFTS is not specific for elimination of pain from the contained structures and can influence pain from the oblique and straight sesamoid ligaments.⁵ Moreover, in some horses with DFTS pathology, the response to perineural analgesia is better than to intrathecal analgesia.

Characteristics of synovial fluid of the DFTS do not vary from those of the distal limb synovial joints. Normal synovial fluid is clear yellow and has a nucleated cell count of 770 cells/mcL or less and a total protein concentration of 1.0 g/dL or less.⁴ More sophisticated analysis of the synovial fluid for molecular markers offers the prospect of better preoperative identification of the presence of intrathecal tendon pathology.⁶

IMAGING OF THE DIGITAL FLEXOR TENDON SHEATH

Diagnostic ultrasonography is by far the most commonly used technique for evaluating the DFTS. The DFTS is first encountered at level 3A and continues distally to level P1C and beyond (see Chapter 16).⁸ The PAL can be demonstrated in normal horses as a thin (1 to 2 mm) echogenic band immediately adjacent to the palmar surface of the SDFT at level 3C. The proximal digital annular ligament and distal digital annular ligament usually cannot be recognized in the palmar midline, unless they are abnormally thickened. The vinculum of the SDFT at the level of the PSB is easily identifiable by ultrasonography, but the distal mesotendon of the DDFT in the phalangeal region is only occasionally visible, usually when distention of the DFTS provides negative contrast (see Figure 70-2, B). A normal synovial reflection or mesotendon joins the lateral and medial borders of the DDFT in the proximal recess of the DFTS, which should not be mistaken for an adhesion (see Figure 70-2, A). The thickness of the DFTS can be assessed at levels 3A and 3B, where the capsule is identifiable as an echogenic band dorsal to the DDFT and the manica flexoria.

Before the widespread use of ultrasonography for examining the soft tissues of the DFTS, negative contrast radiography was described for the assessment of tenosynovitis and annular desmitis.⁹ To perform this technique, a

tourniquet is applied distal to the carpus in a standing or anesthetized horse; 50 to 100 mL of air is injected into the DFTS; and another 200 to 300 mL of air is injected subcutaneously. Sometimes extra air is injected between the SDFT and DDFT at the midmetacarpal level. One postinflation lateromedial radiograph obtained at half the milliamperes per second value of standard skeletal exposure for this region is normally sufficient to make an accurate diagnosis. Although this technique effectively demonstrates the thickness of the PAL, its use has become superseded by the widespread availability of diagnostic ultrasonography.

Survey radiography of the DFTS is performed to demonstrate evidence of intrathecal air or gas caused by a penetrating wound, the presence of metaplastic mineralization of injured soft tissue structures, or concurrent pathological conditions of the bone. Positive contrast radiography¹⁰ may provide the most conclusive evidence of wound communication with the synovial space and may also provide additional information in the diagnosis of synoviocles associated with the DFTS. Although fistulography and filling of the intrathecal space with sterile iodine-based contrast medium is diagnostic of communication between the wound and the DFTS, we prefer to access the DFTS by placing a needle at a site remote from the wound. This minimizes the risk of forcing bacteria or foreign material present in the deeper layers of the wound into the synovial space. Using a remote site further avoids the risk of inadvertently introducing bacteria while passing the needle through an area of cellulitis into the synovial cavity. Infiltration of 10 to 20 mL of sterile contrast medium followed by manipulation of the digit should result in flow of contrast medium from the wound and can be demonstrated radiologically (Figure 74-1).

Tenoscopy is the ultimate imaging modality for evaluating the internal structures of the DFTS.¹¹ An endoscope is introduced routinely in the proximal collateral recess of the sheath, 1 cm distal to the base of the PSB and 1 cm palmar or plantar to the neurovascular bundle, but access to other synovial recesses is also possible (see Chapter 24). This approach allows for a complete examination of the DFTS and its contents, except for the palmar surface of the SDFT, unless substantial thickening of any of the annular ligaments or extensive subcutaneous fibrosis has occurred. Access in ponies and cob-types with very thick skin can also be difficult. The approach also facilitates therapeutic maneuvers within the DFTS, such as PAL desmotomy, adhesiotomy, synovial mass removal, and debridement of fibrillated or torn areas of the digital flexor tendons, manica flexoria, or intersesamoidean ligament.

Magnetic resonance imaging has superior soft tissue contrast and has been of use to identify occult lesions not seen radiologically or ultrasonographically such as isolated adhesions, lesions of the SDFT or DDFT, and injury of the distal digital annular ligament.

DISEASES OF THE DIGITAL FLEXOR TENDON SHEATH

Noninfectious Tenosynovitis

Etiopathogenesis

Acute noninfectious tenosynovitis is a traumatic synovitis/capsulitis of the sheath lining. As for joints, a traumatic

Fig. 74-1 • Lateromedial radiographic image of the fetlock region. A positive-contrast tenogram of the digital flexor tendon sheath, followed by manipulation of the digit, resulted in flow of radiodense contrast medium from a wound (arrow).

synovitis/capsulitis can be caused by accumulative low-grade trauma associated with normal exercise, acute trauma associated with direct impact force (e.g., overreach), or an abnormal force outside the normal range of movement of the fetlock region (e.g., hyperextension). Synovitis/capsulitis is more frequently secondary to damage to the internal or supporting structures of the DFTS, such as disruption of the visceral or parietal synovial layers, tearing of the vincula, tearing of the sheath wall with herniation or synoviocle formation, central or marginal damage to the flexor tendons, tearing of the manica flexoria, and spraining of the PAL or proximal digital annular ligament. Each of these complicating conditions is likely to result in continuous irritation of the sheath and cause chronic tenosynovitis. Chronic tenosynovitis may be associated with villonodular thickening of the sheath lining, especially in the proximal recess; adhesion formation between the visceral and parietal synovial lining; and fibrosis with reduced elasticity of the DFTS capsule. When these conditions are present, a self-perpetuating cycle occurs of improvement with rest, followed by repeated inflammation with exercise. This results in increased inflammation and lameness, further fibrosis, and eventually thickening of the PAL and stenosis of the fetlock canal (see the following discussion of PAL syndrome). *Complex tenosynovitis* has been defined as tenosynovitis with thickening of the PAL, synovial distention, and adhesions or synovial masses, or both (Figure 74-2).¹² Windgalls, especially those occurring bilaterally in the hindlimbs, are another form of low-grade chronic tenosynovitis. Although lameness is not usually a feature of windgalls, the synovial effusion is still likely

to reflect the presence of low-grade chronic synovitis of the DFTS, caused by the continuous stress of use-induced overloading.

Diagnosis

Acute tenosynovitis is characterized by a sudden onset of mild to severe lameness, accompanied by DFTS distention that can be palpated in the proximolateral and proximo-medial pouches of the sheath and in the palmarodistal recess between both branches of the SDFT. The palmar or plantar region of the fetlock has increased skin

temperature, and forced flexion of the fetlock is painful and exacerbates lameness. Chronic tenosynovitis produces similar signs, except for the signs of acute inflammation, although repeat injury may cause these signs to be superimposed on an established tenosynovitis. Disproportionate distention and pain in different regions of the DFTS can reflect the site of the primary pathology; pain on palpation of the proximal aspect of the DFTS is present when there is tearing of the digital flexor tendons in this location.

Ultrasonographic examination is essential for identifying any primary pathology responsible for the tenosynovitis, such as adhesions and complicating injuries of the digital flexor tendons (see Figure 69-8, A), the interosseomedial ligament, or annular ligaments, and to document the staging of the condition.¹³ DFTS effusion may also accompany injury to the intrathecal part of the SDFT associated with a classic bowed tendon (see Chapter 69). However, intrathecal tendon injuries occur more commonly as focal core lesions in the DDFT (see Chapter 70) or as longitudinal tears of the SDFT, DDFT, or manica flexoria. DDFT tears usually involve the lateral or medial borders of the tendon in the forelimb; hence oblique ultrasonographic views can sometimes identify defects on these borders, although they are easily missed. Oblique images are also required to image the abaxial margins of the SDFT. Manica flexoria tears are more frequently seen in hindlimb tenosynovitis and are also easily missed using transverse ultrasonographic images because the tears are usually incomplete and located at the site of attachment of the manica flexoria to the SDFT. Recently, we have found that a midline longitudinal scan immediately proximal to the PSBs provides the best image for identifying instability and/or thickening of the manica flexoria that accompanies tears (Figure 74-3). However, negative ultrasonographic findings do not preclude a tear in the manica flexoria.

Ultrasonographically, tenosynovitis has three progressive stages.¹⁴ Symmetrical distention of the DFTS without

Fig. 74-2 • Stage 3 tenosynovitis of the digital flexor tendon sheath with adhesions and synovial mass formation (*arrow*).

Fig. 74-3 • Longitudinal ultrasonographic images from the midline immediately proximal to the metatarsophalangeal joint (*distal to the left*). The left limb has a normal manica flexoria (*arrow*). In the right hindlimb, the manica flexoria is displaced from the dorsal surface of the deep digital flexor tendon and is thickened (*arrow*).

evidence of synovial proliferation represents stage 1, or the effusive stage of synovitis. More pronounced, often asymmetrical distention of the proximal pouch, which feels firm on palpation and is accompanied by synovial proliferation, is stage 2. In stage 3 synovitis, extensive synovial proliferation occurs with or without adhesion formation in the sheath. Adhesions are manifest as echogenic material between the tendon and wall of the DFTS and can be more easily seen when fluid from marked distention provides negative contrast. Care must be taken to avoid undue pressure on the ultrasound transducer, which will obliterate this fluid from the field of view. However, the presence of adhesions can be easily overestimated with ultrasonography.

Treatment

An important aspect of the decision making is the differentiation of primary versus secondary tenosynovitis. Treatment of horses with acute primary tenosynovitis consists of rest with bandage immobilization, cold therapy, and systemic antiinflammatory medication. The latter can be commenced with a single systemic dose of a short-acting corticosteroid (dexamethasone phosphate [0.06 mg/kg intravenously] or betamethasone phosphate [0.04 mg/kg intravenously]), followed by a 5-day systemic course of flunixin meglumine (1.1 mg/kg daily) or phenylbutazone (4.4 mg/kg daily). After the initial 7 to 14 days, in-hand-walking can be resumed for 2 weeks, before returning the horse to riding. If the clinical signs have not resolved after 7 to 14 days, intrathecal injection of hyaluronan and a corticosteroid (40 to 80 mg of methylprednisolone acetate or 10 mg of triamcinolone acetonide) can be considered provided that no primary cause, such as tendon injury, of the tenosynovitis is suspected. A potential adverse effect of this treatment is that the intrathecal injection of a corticosteroid will interfere in the healing of an injured tendon and may enable a horse with a complicating digital flexor tendon injury to return to soundness temporarily, thereby

potentially allowing it to exacerbate the underlying cause for continued irritation of the DFTS. Therefore the clinician should attempt to ensure, with the aid of ultrasonographic evaluation, that no injuries to the digital flexor tendons in the DFTS exist before intrathecal corticosteroids are administered. However, one should remember that many marginal tears of the SDFT or the DDFT within the DFTS may not be identifiable with ultrasonography, especially if they are located at the level of the ultrasonographic blind spot beneath the ergot. Evaluating specific images (see above), measuring the cross-sectional area of each digital flexor tendon (see Chapter 16), and comparing the same measurements in the contralateral limb may help veterinarians recognize subtle digital flexor tendon injuries, without obvious changes in echogenicity. One of the Editors (SJD) treats suspected primary DFTS tenosynovitis by intrathecal administration of corticosteroids immediately after recognition of lameness; persistence of lameness or recurrence of lameness within 2 to 3 weeks is a good indicator that there may be a more complicated injury.

However, in horses that are unresponsive to this treatment or in horses with suspected primary causes (such as those characterized by thickening and fibrosis of the PAL, adhesions, synovial masses, or tears to the digital flexor tendons), tenoscopic exploration of the DFTS is warranted. Tenoscopy provides both diagnostic and therapeutic capabilities. In forelimb injuries, the majority of the tendon lesions involve marginal tears of the lateral, most commonly, or medial margins of the DDFT proximal to the base of the PSBs (Figure 74-4).^{14,15} These tears are most appropriately managed by debridement of the prolapsed tendinous tissue. Open suture repair of the tears is invasive, does not offer any improvement over tenoscopic debridement, and is not recommended. In hindlimbs, the more common abnormality (with the same clinical signs) is tearing of the lateral or medial attachments of the manica flexoria to the SDFT (Figure 74-5).¹⁵

Fig. 74-4 • Oblique transverse ultrasonographic image (*left, lateral to the left*) showing a lateral border tear of the deep digital flexor tendon (DDFT) and (*right*) the tenoscopic appearance with the torn fibers prolapsing from the border of the tendon (*arrow*).

Fig. 74-5 • Tenoscopic view of a manica flexoria tear (*top images; arrows*). The top left image shows a partial tear viewed from the abaxial part of the proximal aspect of the digital flexor tendon sheath. The top right image shows an almost complete tear taken with the endoscope positioned between the manica flexoria and the deep digital flexor tendon (DDFT). The bottom image shows the manica flexoria after resection. *MF*, Manica flexoria.

These horses are managed by removing the manica flexoria in its entirety (see [Figure 74-5](#)). This is achieved using medial and lateral endoscopic portals and medial and lateral instrument portals to introduce a hook knife that is used to transect all remaining attachments of the manica flexoria to the medial and lateral borders of the SDFT. The manica is then pulled through one of the instrument portals (where enlargement of the skin portal is usually necessary) before the proximal synovial attachment is transected to complete removal.

Prognosis

The prognosis for horses with acute, uncomplicated non-infectious tenosynovitis is favorable if treatment starts immediately. The prognosis for those with complex tenosynovitis with synovial masses and adhesions is more guarded but lameness can resolve after tenoscopic debridement and PAL desmotomy. In one report, 18 of 25 horses

returned to athletic soundness.¹² Of those horses with a primary tendon injury, the prognosis depends more on this primary pathology. Only 40% of horses with longitudinal tears of the DDFT within the DFTS returned to the same level of exercise after debridement, with the prognosis being even worse (18%) if the tears were long.¹⁵ This is similar to those horses with DDF tendonitis within the DFTS not associated with marginal defects, where seven of 24 horses (29%)¹⁶ made a full recovery (see Chapter 70). However, one of the Editors (SJD) has recently had much better success with management of horses with core lesions by intralesional injection of cultured mesenchymal stem cells. Seventy-six percent of horses with excision of manica flexoria tears returned to the previous level of work.¹⁵ Negative prognostic indicators in addition to the site of the tear were chronicity and marked preoperative distention of the DFTS.¹⁵ However, conservative management of horses with acute small marginal tears of the SDFT is often successful.

Infectious Tenosynovitis

Infectious tenosynovitis is a critical condition in the horse because of the severity of lameness, the difficulty in eliminating infection from the DFTS, and the high risk of long-term sequelae such as adhesions and fibrosis, which contribute to permanent lameness even if infection is eliminated.

Etiopathogenesis

The most common cause of DFTS infection is a penetrating wound. Occasionally, small puncture wounds that readily seal over may not be recognized as the cause of acute, severe lameness associated with DFTS infection. Penetrating injuries to the DDFT in the pastern region are frequently undiagnosed at the outset.¹⁵ Most penetrations in this region lead to infectious tenosynovitis and rarely infectious tendonitis of the DDFT. However, occasionally a traumatic penetration may enter the DDFT through its distal mesotendon and form a localized abscess that remains separate from the intrathecal space, thereby preventing infectious tenosynovitis. Infection may also occur after intrathecal injection or surgery of the PAL. Rarely, hematogenous spread of infection to the digital sheath may result from bacteremia.

Diagnosis

Heat and effusion of the DFTS and severe lameness are classic signs of DFTS infection. Typically horses are reluctant to put the heel of the affected limb to the ground. Exception to this may be seen in horses with an open wound to the DFTS that allows free drainage of infected synovial fluid. The reduction in intrathecal pressure and bacterial numbers provided by continuous flow of synovial fluid may reduce inflammation and lameness considerably. With a closed wound, however, the affected sheath is grossly distended. Generalized and painful lower limb edema caused by cellulitis associated with the entry wound may hinder specific palpation that would aid in identifying DFTS distention. Horses with penetrating injuries to the DDFT in the pastern region are characterized by moderate to severe lameness, localized swelling in the pastern, and a pronounced pain response to focal pressure on the palmar surface of the DDFT in the pastern region.

Radiography and ultrasonography are useful to recognize complicating factors such as osteitis or osteomyelitis, concurrent tendon injury, foreign bodies, and infectious tendonitis. Contrast radiography may help confirm a penetrating tract. In the absence of a penetrating tract, confirmation of the diagnosis relies on synovial fluid analysis. This should be performed as early as possible when DFTS infection is suspected. A total nucleated cell count greater than or equal to 30,000/ μ L, with more than 90% neutrophils, and a total protein concentration greater than or equal to 4.0 g/dL are considered pathognomonic for infection. Attempts should be made to identify bacteria by Gram stain and culture. Using broth culture bottles enhances the likelihood of obtaining a positive culture. Bacteria cultured from wounds or draining tracts are not representative of intrathecal bacterial populations. Positive cultures have been reported from 67% to 81% of horses with infectious tenosynovitis.¹⁸ Of the positive cultures in one study, 46% were mixed cultures. *Streptococcus* and *Klebsiella* species were the most common isolates from adult

horses with infectious tenosynovitis.¹⁹ In another study, iatrogenic synovial infection was more likely to result in a pure culture of *Staphylococcus aureus*, whereas Enterobacteriaceae were most frequently cultured from synovial sepsis caused by a penetrating wound.²⁰

Treatment

As for joint infections (see Chapter 65), the principles of antimicrobial therapy, synovial debridement, and drainage apply to infections of the DFTS. Treatment of infectious tenosynovitis must consist of aggressive intrasynovial and systemic broad-spectrum antimicrobial therapy with lavage of the sheath. Regional intravenous perfusion of antibiotics,²¹ slow-release antibiotic-depot systems in collagen or polymethylmethacrylate,^{22,23} and antibiotic infusion pumps (MILA Joint Infusion System; MILA International, Inc., Florence, Kentucky, United States)²⁴ all have been used to maximize the intrathecal concentration of antibiotics over a protracted period.

The ideal surgical treatment for DFTS infection consists of tenoscopic debridement of fibrin, foreign material, adhesions, and synovial masses along with simultaneous lavage.²⁵ Needle lavage is usually relatively less effective at achieving resolution of the infection because of the blind-ending pouches in the DFTS. Transection of the PAL can relieve pain that results from excessive fluid accumulation and fibrosis and thickening of the sheath wall in horses with chronic infectious tenosynovitis. This is best performed through a tenoscopic approach to minimize the risk of wound dehiscence that accompanies a transcutaneous approach. After tenoscopy, portals usually are closed but can be left open for continued drainage if desired with chronic infection. Indwelling fenestrated drains may be placed at surgery for continued through-and-through lavage. Fenestrated polyvinylchloride or silicone drains are preferable to Penrose drains because they allow for lavage and drainage. The drain is covered with a sterile dressing under a bulky pressure bandage, and lavage is continued twice daily for 3 to 5 days. Because adhesion formation and fibrosis are the most common causes for surviving horses' failure to return to the intended use, specific recommendations have been made to reduce the incidence of these crippling complications. After removal of the drain and healing of the skin portals, hyaluronan is injected into the sheath at 14-day intervals to reduce adhesion formation. These injections are best started between 7 and 14 days after injury during the time of fibrosis and adhesion formation.

Provided adequate debridement and lavage have been achieved tenoscopically, primary closure of an open DFTS shortly after injury is usually indicated. However, closure may be contraindicated in some horses with extensive contamination and/or inadequate debridement because closure may trap bacteria in the sheath. In such horses, cleaning the wound thoroughly and maintaining it under sterile wraps to allow for healing by second intention to occur may be preferable, or consideration may be given to delayed closure when the wound is sufficiently clean and lameness has resolved.¹⁸

Early passive motion and handwalking exercise were advocated to prevent restriction of range of motion.^{18,19} Elevation of the heel often causes improved weight bearing and ambulation during this period. Cast immobilization of

the distal limb is contraindicated during treatment for DFTS infection if the digital flexor tendons are intact. Although immobilization limits recurrent inflammation associated with continuous movement of the damaged tissues, it limits drainage and promotes the restrictive nature of any scar tissue and adhesions. However, immobilization effects more rapid soft tissue healing and therefore is indicated to decrease wound motion once infection has been resolved. A commercial or homemade splint is adequate for immobilization.

Prognosis

Horses with wounds of the DFTS have a good prognosis for return to soundness if the wound is diagnosed and treated before infectious tenosynovitis develops. If infection occurs, the prognosis is guarded. Although the prognosis for elimination of infection and survival was described as good in most studies (as high as 100% in one study²⁰), another study reported a 45% failure of return to soundness and intended use for horses with infectious DFTS tenosynovitis. Even if infection can be resolved successfully, fibrosis, adhesions, and occasionally tendon rupture or osteomyelitis of the PSB may cause permanent lameness. Most authors believe that the chance of resolution is related directly to the duration of infection.¹⁸

PALMAR ANNULAR LIGAMENT SYNDROME

Etiopathogenesis

The PAL counteracts a tendency of the PSBs to move in a dorsal and abaxial direction during weight bearing. The medial and lateral branches and the extensor branches of the SL effect strong traction in a dorsal direction at the respective insertion sites on the abaxial surface of the PSBs during extension of the fetlock joint. This traction is balanced by the intersesamoidean ligament and the PAL.¹ The role of disease of the PAL as a cause of lameness is a subject of debate. Thickening of the PAL has been associated with lameness in a number of different diseases of the DFTS and associated structures. All these diseases have characteristic clinical manifestation of distention of the DFTS and thickening of the PAL in common and therefore as a group have been referred to as *palmar annular ligament syndrome*. Other terms that have been used to describe this clinical presentation include *stenosis of the fetlock canal*, *palmar annular ligament constriction*, *fetlock canal dysfunction*, and *stenosing palmar ligament desmitis*. The role of desmopathy in this syndrome is supported by histopathological evidence of chronic inflammation and repair tissue in PAL biopsies from horses with clinical disease.²⁴⁻²⁸ Undoubtedly, however, the cause of PAL desmitis is multifactorial. Direct external trauma to the PAL may be caused by laceration or by direct impact (e.g., overreach). Overextension of the fetlock at high speed is likely to be associated with high tensile forces in the PAL and may lead to injury and failure of the PAL under tension. Excessive tendon swelling within the DFTS, although uncommon, may result in sustained pressure on and inflammation of the PAL (see Chapter 69, Figure 69-2). Finally, chronic inflammation of the DFTS (noninfectious or infectious tenosynovitis) leads to fibrosis and thickening of the fibrous part of the DFTS capsule, which includes the PAL. In some horses the subcutaneous connective tissue in the area of the PAL becomes greatly

thickened and fibrotic. Once an inflammatory response is initiated, the PAL becomes thickened, whatever the cause. Thickening of the PAL reduces the space within the fetlock canal and results in a relative stenosis. The continuous pressure from the tendons associated with this relative stenosis is a source of trauma and perpetuates this sequence of events, leading to further inflammation, fibrosis, and thickening of the PAL and persistent pain (Figure 74-6).

A positive relationship exists between incidence of PAL desmitis and increasing age of the horse, a predisposition in some breeds (Paso Fino and Warmbloods), and location (especially hindlimbs in the mentioned breeds).²⁶ Rarely, small avulsion fractures may occur at the site of insertion of the PAL to the palmar border of a PSB after overextension injury or local trauma (see page 754 and Figure 72-17).²⁹

Diagnosis

Occasionally, acute lameness may be caused by PAL injury without tenosynovitis. Clinical signs include localized heat, swelling, and pain on palpation of the palmar aspect of the fetlock. The clinical signs of the more common chronic PAL syndrome are characteristic. Horses have long-term, persistent, mild to moderate lameness that improves little with rest and worsens with return to exercise. A fetlock flexion test exacerbates lameness. DFTS distention with a notch in the palmar outline of the fetlock is virtually pathognomonic for PAL syndrome (Figure 74-7). This notch is caused by the inability of the DFTS to distend at the site of intimate attachment between the SDFT and the dorsal surface of the thickened, inelastic PAL. Sometimes enlargement of the PAL or the overlying subcutaneous tissues results in a localized bulge rather than a notch over the palmar aspect of the fetlock region. Extension of the affected fetlock often is decreased during weight bearing at walk or trot, and occasionally affected horses are reluctant to put the heel of the affected foot to the ground. This splinted fetlock posture is assumed by the affected horse to decrease pressure of the digital flexor tendons on the inflamed PAL.

Lameness often is improved, but not always completely eliminated, by intrathecal analgesia. The response to a low four- or six-point nerve block is often better. Sometimes a palmar nerve block performed at the base of the PSBs improves lameness. Fibrosis of the PAL and DFTS may result in mechanical gait restriction, which cannot be abolished totally by regional analgesia.

Various imaging techniques can be used to support the clinical diagnosis of PAL desmitis. In horses with chronic lameness, enthesioid new bone may be present at the PAL insertions on the palmar border of one or both PSBs. Air tenography or ultrasonography must be used to demonstrate thickening of the PAL or the overlying subcutis. The ultrasonographic appearance of a diseased PAL differs between affected horses and may be helpful in differentiating the etiopathogenic mechanisms behind each injury. An unaffected PAL can be difficult to identify because it is only 1 to 2 mm thick, and imaging the ligament in the sagittal midline is complicated by the vinculum between the PAL and the SDFT, which makes resolution of the ligament difficult. The PAL is identified most easily at its attachment to a PSB by tilting the transversely positioned

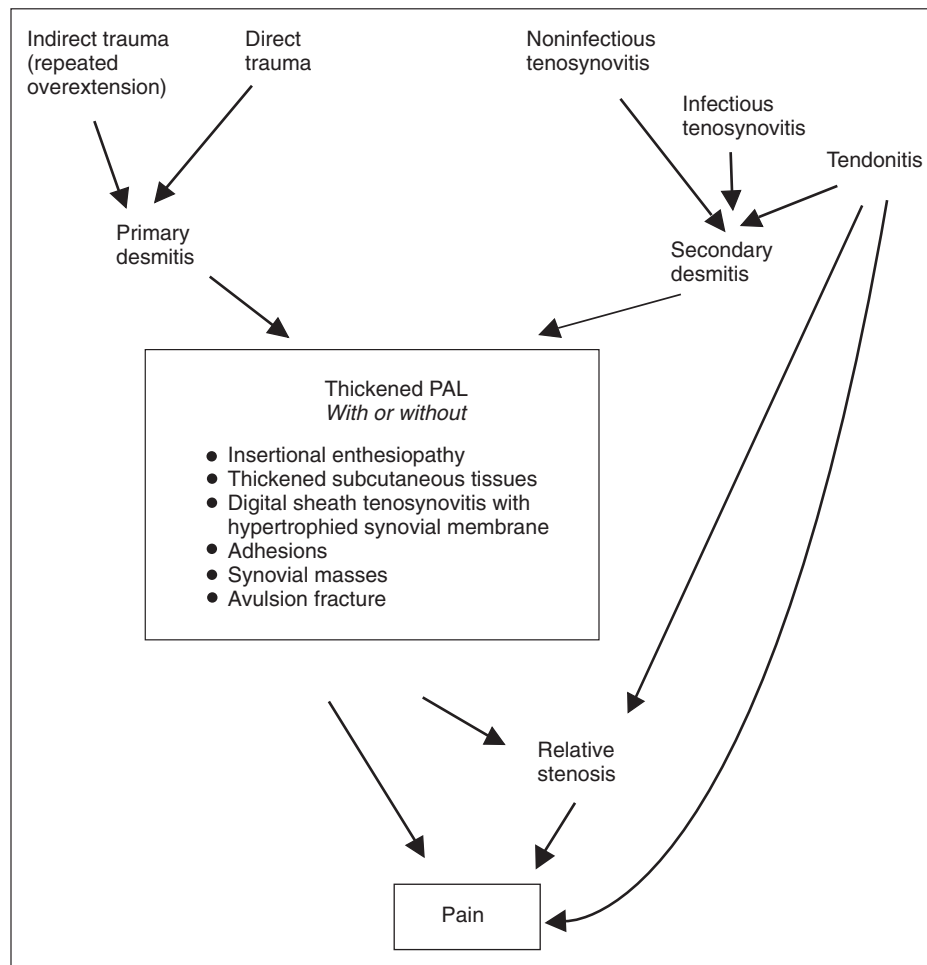

Fig. 74-6 • Etiopathogenesis of palmar annular ligament (PAL) syndrome.

Fig. 74-7 • Digital flexor tendon sheath distention with characteristic notch in the plantar outline of the fetlock region (arrow) in a horse with palmar annular ligament syndrome.

transducer laterally or medially from the palmar midline. The ligament then can be followed toward the midline. Several measurements of the thickness of the PAL should be made on transverse and longitudinal images to obtain reliable data. Because of the difficulties in consistently identifying the PAL, some clinicians have proposed measuring the distance between the palmar surface of the SDFT and the skin surface.³⁰ Any increase in thickness more than 5 mm is considered to be abnormal. However, three different structures contribute to this measurement, each of which can be thickened to varying degrees in different pathology and in different breeds: the subcutaneous tissues, the PAL, and the parietal and visceral layers of the DFTS.

Primary Palmar Annular Ligament Thickening

Primary PAL thickening is characterized by ultrasonographic evidence of thickening of the PAL, without evidence of pathological conditions of the structures within the DFTS (Figure 74-8). Although tenosynovitis is present, the synovial lining of the sheath is not substantially thickened. With acute desmitis, the ligament is enlarged and contains focal hypoechoic areas, or it is diffusely hypoechoic. PAL thickening may be accompanied by extensive subcutaneous fibrosis. This condition occurs more

Fig. 74-8 • Transverse ultrasonographic image of the distal metacarpal region at the level of the proximal sesamoid bones. There is primary enlargement of the palmar annular ligament. The palmar annular ligament (X to X) measured 7 mm in thickness. *SDFT*, Superficial digital flexor tendon; *DDFT*, deep digital flexor tendon.

Fig. 74-10 • Transverse ultrasonographic image of the distal metacarpal region. There is subcutaneous fibrosis, with minimal thickening of the palmar annular ligament (PAL), associated with clinical signs of PAL syndrome. Although the distance from the skin to the plantar surface of the superficial digital flexor tendon amounts to 9.19 mm (+ to +), the PAL is only 1.59 mm thick. *SDFT*, Superficial digital flexor tendon; *DDFT*, deep digital flexor tendon.

Fig. 74-9 • Transverse ultrasonographic image of the distal metacarpal region at the level of the proximal sesamoid bones. There is thickening of the palmar annular ligament (+ to +) and the synovial membrane of the digital flexor tendon sheath (X to X). *SDFT*, Superficial digital flexor tendon; *DDFT*, deep digital flexor tendon.

commonly in hindlimbs than forelimbs, and ponies and cob-type horses seem particularly prone. Thickening may be present bilaterally in a unilaterally lame horse but is always greater in the lame limb. Some horses have developed sequential lameness in more than one limb.

Primary Tenosynovitis with Secondary Palmar Annular Ligament Thickening

Ultrasonographic differentiation between secondary PAL thickening and primary desmitis is sometimes difficult, but the synovial lining of the DFTS usually is considerably thickened, including the lining at the level of the PAL

(Figure 74-9). Horses with chronic, complex tenosynovitis may have adhesions and synovial masses.

Subcutaneous Fibrosis with a Normal or Minimally Enlarged Palmar Annular Ligament

Subcutaneous fibrosis in the region of the PAL can produce clinical signs similar to those of PAL thickening and often can be distinguished only by careful ultrasonographic imaging (Figure 74-10). These injuries frequently are caused by focal trauma to the PAL area and can involve portions of the PAL and the surface of the underlying SDFT.

Tendon Injuries with Secondary Palmar Annular Ligament Thickening

Injuries of the SDFT, manica flexoria, or DDFT within the fetlock canal may result in inflammatory tenosynovitis, which also can lead to PAL thickening. Although tendonitis usually can be diagnosed by ultrasonography, many focal longitudinal tears of the SDFT and DDFT remain undetected, especially if they are located at the level of the ultrasonographic blind spot beneath the ergot.

Treatment and Prognosis

Treatment of horses with acute PAL desmitis with rest and topical antiinflammatory medication often results in rapid resolution of lameness and swelling. In many horses, however, PAL desmitis becomes a chronic condition, treatment of which requires surgical release (desmotomy) of the inflamed and thickened PAL. Desmotomy resolves pain from traction on the ligament during weight bearing and eliminates pressure from structures within the stenotic fetlock canal on the PAL. This can be performed

via a traditional surgical approach, using an open or a minimally invasive technique. A minimally invasive approach through a small skin incision in the proximal recess of the DFTS is simple and quick, but subcutaneous transection of the PAL is performed blind (see Chapter 69). However, confirmation of a relative stenosis within the fetlock canal in these horses is difficult preoperatively unless movement of the tendons through the canal is visibly impeded. The best evaluation is achieved tenoscopically, albeit in a non-weight-bearing limb, by assessing the ease with which a 5-mm endoscopic cannula can be passed from distal to proximal through the fetlock canal. This has an additional benefit of enabling the surgeon to simultaneously evaluate the entire DFTS and treat any concurrent pathological conditions, such as longitudinal tendon tears, adhesions, and synovial masses, which may be the primary cause of the PAL thickening. Desmotomy of the PAL can then be achieved tenoscopically either with a slotted canula used for carpal tunnel release in people (Smith & Nephew Dyonics Inc., Andover, Massachusetts, United States) or by direct tenoscopic evaluation and use of a freehand, hook knife or Metzenbaum scissors.¹¹ A minimally invasive approach (incisional or tenoscopic) decreases the risk of wound dehiscence and fistulation and allows for earlier, safe return to exercise. If a traditional open approach is used, particular attention should be paid to careful closure of the subcutaneous tissues in two layers, as well as of the skin, to minimize the risks of synovial fistulation and wound dehiscence. Contrary to previous reports, our opinion is that horses that have undergone an open surgical approach to the DFTS should not be returned to exercise before healing of the incision is complete. Instead the horse should be confined to a stable and the limb enclosed in a firm, padded bandage until the time of suture removal at 2 weeks. After this, a gradually increasing exercise regimen can be initiated (2 weeks walking in hand, 4 weeks lunging) before return to ridden work. Some authors report the need for 4 to 6 months of rest and controlled exercise before soundness can be expected.²⁹

Specific recommendations for treating PAL syndrome can be made according to the specific ultrasonographic characteristics. Unresponsive primary desmitis requires PAL desmotomy. In horses with primary tenosynovitis with secondary PAL desmitis, therapeutic planning should be aimed at discovering and treating the primary cause of the synovitis (e.g., infection, traumatic tendon injuries, and hypertrophic synovitis), with or without the need for PAL desmotomy. Tenoscopy is indicated in these horses.

If the stenotic effect is caused by extensive subcutaneous fibrosis over the PAL, conservative management with rest and antiinflammatory medication is occasionally successful in resolving lameness. However, if this approach fails to bring resolution, surgical release of the PAL and subcutaneous ring of fibrosis may resolve lameness. Occasionally, complete resection of the PAL is performed in horses in which there is persistent focal and intense pain over the PAL. The use of a C-shaped skin incision to create a medially or laterally based flap and preservation of the subcutaneous tissues, including the fat of the ergot, followed by careful closure and short-term (2 to 4 weeks) cast immobilization can give remarkably good cosmetic and

Fig. 74-11 • Transverse ultrasonographic image of the proximal pastern region of a hindlimb. The distance from the skin surface to the plantar surface of the superficial digital flexor tendon (SDFT) (+ to +) is enlarged to 8 mm in this horse with chronic desmitis of the proximal digital annular ligament. DDFT, deep digital flexor tendon; SSL, straight sesamoidean ligament.

functional end results (Figure 74-11). However, resection should only be considered for horses with primary PAL pathology unresponsive to conservative management. Lameness associated with small avulsion fractures of the palmar border of the PSB may be relieved by PAL desmotomy near its insertion site. In one study, however, three horses regained soundness without surgery after 3 to 6 months of controlled exercise.²⁷ Finally, the resolution of tendonitis of the SDFT or DDFT within the DFTS may be assisted by PAL desmotomy, although the benefit of surgical treatment has proved less obvious in these horses.^{13,30} Despite these reports, PAL desmotomy has proved useful in managing SDF tendonitis in Standardbreds (see Chapter 69).³¹ The prognosis after surgical desmotomy is generally favorable for soundness in horses with desmitis of the PAL without tendonitis and has ranged from 64% to 87%.^{12,29} Factors with a negative influence on outcome are the presence of tendonitis, infection, or adhesions. Although in one study adhesions reduced the return to soundness to 44% after PAL desmotomy,³⁰ a different study showed that 72% of horses with complex tenosynovitis made a full recovery after tenoscopic debridement and PAL desmotomy.¹² In a study of 71 horses with chronic PAL desmopathy with or without subcutaneous fibrosis, 22 of 44 (50%) returned to full athletic function, whereas only eight of 27 (33%) horses with concurrent tendon pathology returned to full function.²⁷

DISEASES OF THE INTERSESAMOIDEAN (PALMAR) LIGAMENT OF THE FETLOCK

Etiopathogenesis

When the fetlock overextends, the proximal scutum slides distally to the metacarpal condyle and its palmar surface undergoes pressure from the flexor tendons. Moreover, in this position the distal medial and lateral extensor branches of the SL induce high tension on the abaxial surface of the PSBs, thus creating high tension on the intersesamoidean ligament.³² The effect of these forces could provide a

biomechanical explanation for injuries to the intersesamoidean ligament. Post mortem examination of 305 pairs of PSBs revealed radiological changes in 25.8% and gross abnormalities of the intersesamoidean ligament in 25.9%,³³ although premortem recognition of intersesamoidean ligament pathological conditions causing lameness has been considerably less common.³⁰ Diseases of the intersesamoidean ligament have been classified by the ultrasonographic and radiological appearance as rupture of the intersesamoidean ligament, avulsion fracture of the intersesamoidean ligament from the PSBs, desmitis of the intersesamoidean ligament (noninfectious and infectious), and enthesopathy of the intersesamoidean ligament.^{32,35-37} Infectious desmitis and axial osteomyelitis of the PSBs usually are associated with infectious arthritis of the fetlock joint or infectious tenosynovitis of the DFTS. Which condition precedes the other is not always obvious. If infectious desmitis or osteomyelitis is the primary condition, a hematogenous route for the infection is likely.

Diagnosis

Injuries of the intersesamoidean ligament usually cause acute-onset, moderate to severe lameness. Horses with enthesopathy with thinning of the intersesamoidean ligament and erosion of the flexor surface of the corresponding PSB may have a more insidious course. Avulsion fractures of the axial border of the PSBs often are accompanied by fetlock effusion, usually involve the lateral PSB, and usually occur in conjunction with a displaced lateral condylar fracture of the third metacarpal bone.³¹ Lameness accompanying these conditions is improved, but not always abolished, by intrasynovial analgesia of the fetlock joint or the DFTS and is eliminated by a low four-point block. Scintigraphy may be required to find the exact site of the pathological condition. In horses with suspected infectious desmitis or osteomyelitis, cytological examination of synovial fluid of the fetlock joint or DFTS often, but not always, indicates synovial infection.

Diagnosis of injury to the intersesamoidean ligament and associated structures mainly is based on abnormal imaging features. Evidence of osseous fragmentation or radiolucency along the axial border of the PSB, predominantly centered at the proximal half of the intersesamoidean space, indicates desmitis, enthesopathy with osteitis, avulsion fracture, or osteomyelitis. Evidence of osteolysis also may be observed along the palmar surface of the PSBs in association with enthesopathy of the intersesamoidean ligament. Ultrasonographic abnormalities include enlargement of the distance between both PSBs with intersesamoidean ligament rupture (>6 mm), enlargement of the intersesamoidean ligament, and alteration of the echogenicity within the intersesamoidean ligament in horses with desmitis, and asymmetrical reduction in the thickness of the intersesamoidean ligament and irregular bony outline to the palmar surface of a PSB in association with enthesopathy.

Treatment and Prognosis

No effective treatment exists for rupture of the intersesamoidean ligament with abaxial displacement of the PSB or for enthesopathy with thinning and degeneration of the intersesamoidean ligament within the DFTS, and the prognosis for soundness in either situation is grave. We have

observed complete recovery in a general purpose riding and jumping horse with intersesamoidean desmitis and a small avulsion fracture of the axial border after a prolonged confinement (6 months). Some reports also have documented favorable outcome for horses with noninfectious desmitis with or without avulsion fracture after arthroscopic removal of fracture fragments and debridement of the osteochondral defect and the associated discolored area of the intersesamoidean ligament.^{35,36} Histological evaluation of the damaged intersesamoidean ligament in these horses revealed chronic inflammation and granulation tissue, with thrombosis of the microvasculature. All horses with noninfectious desmitis treated surgically in one study returned to previous level of performance, although the horses' intended uses were not mentioned.³⁵ Recovery time was 7 to 12 months. In the same study, similar treatment was generally unsuccessful for horses with infectious desmitis and osteomyelitis.³⁵

DISEASES OF THE DIGITAL ANNULAR LIGAMENTS

Desmitis and avulsion fractures of the proximal insertion sites of the proximal digital annular ligament may occur.

Etiopathogenesis

Hyperextension of the fetlock causes differential movement between the SDFT and the proximal phalanx. The proximal digital annular ligament is adhered intimately to the palmar surface of the SDFT in this region, and the proximal digital annular ligament inserts to the proximal phalanx at two levels; thus this differential movement may result in injury of the proximal digital annular ligament or its insertions. Additionally, external trauma to the palmar aspect of the pastern may result in desmitis of the proximal digital annular ligament. Desmitis of the proximal digital annular ligament also has been described in association with injury of the SDFT or infectious tenosynovitis with thickening of the DFTS in horses with infectious desmitis and osteomyelitis.³⁷ It has been suggested that thickening of the proximal digital annular ligament or fibrosis of the subcutaneous tissues on the palmar aspect of the pastern may result in functional constriction of the DFTS and the digital flexor tendons, causing lameness, as is the case with the PAL syndrome.³⁶

Diagnosis

Characteristic clinical findings in horses with desmitis of the proximal digital annular ligament are soft tissue thickening in the palmar pastern region, prominent palmar protrusion of the DFTS distal to the proximal digital annular ligament, and improvement in lameness score by a palmar nerve block or intrathecal analgesia of the DFTS. Ultrasonography provides a definitive diagnosis. The normal proximal digital annular ligament is not visible on ultrasonographic examination, but the palmarodorsal thickness of the combined skin-proximal digital annular ligament layer should not exceed 2 mm. In horses with proximal digital annular desmitis, this distance increased to 4 to 5 mm (see [Figure 74-11](#)).³⁶ It is important to rule out pathological conditions of the digital flexor tendons or

Fig. 74-12 • Lateral radiographic image of a metatarsophalangeal joint. An avulsion fracture fragment (*arrow*) involves the proximal insertion of the proximal digital annular ligament to the plantarolateral border of the proximal phalanx.

distal sesamoidean ligaments as causes of soft tissue swelling in the palmar pastern region (see Chapter 82).

Avulsion fractures of the proximal insertion of the proximal digital annular ligament were seen as a cause of lameness in three horses.³⁷ There were few localizing signs, and diagnosis relied on response to nerve blocks and radiography. Radiographs showed an avulsion fracture fragment at the insertion site of the proximal digital annular ligament on the palmarolateral or palmaromedial border of the proximal phalanx (Figure 74-12).

Treatment

Desmitis of the proximal digital annular ligament with constriction of the DFTS was treated successfully in two horses by desmotomy of the proximal digital annular ligament.³⁶ Two horses with avulsion fractures of the proximal digital annular ligament were treated with 2 months of rest alone, and one horse was treated with 6 weeks of immobilization, followed by 6 weeks of rest. All three horses returned to the previous level of performance.³⁶

Injury of the distal digital annular ligament has recently been recognized as a potential contributor to lameness, either as a primary injury³⁹ or as one of a complex of injuries.⁴⁰ Diagnosis required magnetic resonance imaging. Seven horses with pain localized to the digit had diffuse or focal thickening of the ligament associated with increased signal intensity in T1- and T2-weighted images, with or without concurrent lesions of the DDFT within the adjacent DFTS. Surgical transection of the ligament successfully resolved lameness in those horses in which the injury was considered primary.³⁹ However, it is difficult to conceive how transection was achieved because of the intimate

Fig. 74-13 • Transverse ultrasonographic image over the lateral aspect of the distal metatarsal region of a horse with a synovial ganglion of the digital flexor tendon sheath (DFTS). anatomical relationship between the DDFT and the distal digital annular ligament.

SYNOVIAL GANGLION OR HERNIA OF THE DIGITAL FLEXOR TENDON SHEATH

A synovial hernia or ganglion is a thin-walled cyst originating from a tendon sheath or joint capsule.^{41,42} Hernias of the DFTS result from a traumatic defect in the fibrous layer of the DFTS wall, allowing the synovial lining to herniate through it. Ganglia are thought to result from trauma involving all layers of the sheath wall and are not lined by synovium. Subsequent irritation to the hernial sac causes secretion of synovium and filling of the sac. The opening in some hernial sacs or ganglions can act as a one-way valve that prevents movement of synovial fluid back to the DFTS. Injection of a radiodense contrast medium into the DFTS has resulted in flow of the contrast medium from the parent synovial cavity into the ganglion (Figure 74-13), but not vice versa. We have encountered such a ganglion at the level of the proximolateral recess of the DFTS in five horses, associated with lameness, which was abolished by intrathecal analgesia of the DFTS.⁴³ Diagnostic imaging and surgical exploration revealed a cystic structure, connected to a small slitlike opening in the DFTS wall. Resection and closure of the DFTS wall defect resulted in resolution of lameness. However, such structures can often be seen incidentally unassociated with lameness.

TENDONITIS OF THE SUPERFICIAL AND DEEP DIGITAL FLEXOR TENDONS WITHIN THE DIGITAL FLEXOR TENDON SHEATH

Tendonitis of the SDFT and DDFT within the digital sheath is discussed in Chapters 69 and 70.

Chapter 75

The Carpal Canal and Carpal Synovial Sheath

Sue J. Dyson

ANATOMY

The carpal canal encloses the carpal synovial sheath, which contains the superficial (SDFT) and deep (DDFT) digital flexor tendons. The dorsal wall of the carpal canal is formed by the common palmar ligament of the carpus, which is a thickened part of the fibrous joint capsule that extends distally as the accessory ligament of the DDFT (ALDDFT). Proximally the accessory ligament of the SDFT (ALSDFT) forms the medial wall of the canal. Laterally the carpal canal is formed by the accessory carpal bone and the accessorioquartale and accessorioimetricarpeum ligaments extending distally. The caudal antebrachial fascia, flexor retinaculum, and palmar metacarpal fascia form the palmar aspect of the canal.

The carpal synovial sheath extends from 7 to 10 cm proximal to the antebrachicarpal joint to the midmetacarpal region. The proximal recess is wide and extends between the ulnaris lateralis and lateral digital extensor muscles laterally, but it is firmly supported on the medial aspect by the antebrachial fascia. The distal recess extends between the DDFT and its accessory ligament. If the carpal sheath is distended, swelling can be seen on the lateral aspect of the distal antebrachium and between the DDFT and its accessory ligament, medially or laterally in the metacarpal region.

The ALSDFT arises from the caudomedial aspect of the radius about 10 cm proximal to the antebrachicarpal joint. The ALSDFT is a fibrous fan-shaped band that merges with the SDFT at the level of the antebrachicarpal joint and prevents overload of the SDFT muscle during overextension of the metacarpophalangeal joint. After desmotomy of the ALSDFT in cadaver specimens, strain on the SDFT is increased.¹ At the level of the distal aspect of the radius is an extension from the lateral aspect of the sheath wall between the SDFT and DDFT. At the level of the accessory carpal bone is a mesotendon extending from the lateral aspect of the DDFT to the sheath wall. In clinically normal horses, the amount of fluid within the carpal sheath varies, but it is usually the same bilaterally in each horse.

Fluid within the sheath may be seen readily by ultrasonography between the DDFT and its accessory ligament in normal horses, with no palpable distention of the sheath wall.² Within the proximal part of the carpal sheath, the SDFT and DDFT contain muscular tissue and therefore have hypoechoic regions within them on ultrasonographic examination.³⁻⁵ However, the ALSDFT is uniform in its echogenicity.^{4,5} The position of the accessory carpal bone prohibits ultrasonographic examination from the caudal aspect of the carpus. The carpal sheath and its contents are

evaluated most easily from the distal caudomedial aspect of the antebrachium and carpus and the palmar aspect of the proximal metacarpal region. The heterogeneous echogenicity of the digital flexor tendons proximally can make definitive diagnosis of a tendon lesion difficult, but comparison with the contralateral limb may be helpful. Endoscopic evaluation may yield further information and permit surgical debridement of torn fibers (see Chapter 24).

The transverse ridge of the distal aspect of the radius is at about the same level as the distal physis. Irregular roughening of this ridge may be seen radiologically in normal horses and should not be confused with entheses new bone associated with tearing of the attachment of the ALSDFT further proximally.

Occasionally abnormalities cannot be detected using conventional imaging techniques and magnetic resonance imaging (MRI) is required (see Figure 75-1, B). Normal MRI anatomy of the carpal region has recently been described.⁶

CLINICAL SIGNS

Lameness associated with the carpal synovial sheath is usually accompanied with some distention of the sheath. There may be generalized thickening in the region of the flexor retinaculum. The horse may have restricted flexibility of the carpus, with pain on passive flexion. Alternatively, the horse may resent full extension of the carpus. Rarely, increased pressure within the carpal sheath may result in compromised blood flow within the median artery and reduction in arterial pulse amplitudes in the more distal part of the limb.⁷ Palpation of the structures within the proximal part of the carpal sheath is not possible, but the SDFT, DDFT, and ALDDFT should be assessed carefully in the metacarpal region. Lameness varies from mild to severe and usually is improved by intrathecal analgesia. Clinical investigation should include radiographic and ultrasonographic examinations. In the absence of effusion of the carpal sheath, intrathecal analgesia should be performed to verify the source of pain and the clinical significance of any postulated lesion.

Carpal sheath effusion is not always associated with a primary lesion within the sheath per se but can be seen in association with injuries of the ALDDFT, the proximal aspect of the suspensory ligament, trauma or fractures involving the antebrachicarpal joint, and cellulitis in the distal aspect of the antebrachium, carpus, or proximal metacarpal region (see Chapters 14 and 37).

IDIOPATHIC SYNOVITIS

Synovitis of the carpal sheath usually results in acute-onset, moderate to severe unilateral lameness associated with distention of the carpal sheath. No palpable abnormalities of the digital flexor tendons are apparent. Ultrasonographic examination reveals an abnormal amount of fluid within the sheath but no other structural abnormality. Horses usually respond well to box rest and controlled walking exercise for 4 to 6 weeks, combined with intrathecal administration of corticosteroids and hyaluronan. If lameness is recurrent, synovectomy may be required.

INTRATHECAL HEMORRHAGE

Hemorrhage within the carpal sheath may be idiopathic, result from trauma (e.g., a fall), or occur secondary to either a tear of the SDFT or DDFT, a tear of the ALSDF, or a fracture of the accessory carpal bone (see pages 446 and 780). The horse may be very lame. Diagnosis is confirmed by synoviocentesis. The fluid within the sheath may appear more echogenic than synovial fluid. Careful ultrasonographic examination of the digital flexor tendons and the retinaculum should be performed to identify any primary lesion. In the absence of a primary tendon lesion and fracture, some relief of pain may be gained by draining blood from the sheath. This should be followed by administration of hyaluronan to reduce the risks of subsequent adhesion formation. The horse should be rested for 4 to 6 weeks with administration of nonsteroidal antiinflammatory medication. The prognosis is usually good unless there is underlying primary pathology.

TRAUMA RESULTING IN CHRONIC ENLARGEMENT OF THE CARPAL SHEATH

A horse may have acute distention of the carpal sheath and moderate to severe lameness after a fall. In the acute stage, ultrasonographic examination may reveal only an abnormal amount of fluid within the sheath, but over the next several weeks thickening of the sheath wall and the palmar retinaculum may become apparent, with echogenic fibrous material within the sheath (Figure 75-1). The margin of the SDFT or DDFT may be poorly demarcated, and either

structure may be enlarged. Some horses respond satisfactorily to rest and controlled exercise combined with repeated medication of the sheath with hyaluronan. Early aggressive treatment seems to yield the best results. Passive flexion of the carpus also may be beneficial. If lameness persists for more than 6 weeks, endoscopic evaluation of the sheath and its contents should be considered (see Chapter 24).

DESMITIS OF THE ACCESSORY LIGAMENT OF THE SUPERFICIAL DIGITAL FLEXOR TENDON

Desmitis of the ALSDF is an unusual injury in show jumpers, event horses, dressage horses, and Thoroughbred racehorses, but it seems to occur more commonly in European Standardbred trotters.⁸ The condition is rarely recognized in North American trotters.⁹ Lameness is usually sudden in onset and associated with localized swelling.

Diagnosis is based on ultrasonographic examination. Abnormalities of the ALSDF include enlargement, abnormal fiber pattern, and reduced echogenicity. Enlargement of the ALSDF results in increased distance between the caudal aspect of the radius and the median artery. Injuries to the ALSDF are often seen with other injuries either in the carpal canal, including superficial digital flexor (SDF) tendonitis or thickening of the flexor retinaculum, or elsewhere.^{10,11} These injuries include tenosynovitis of the flexor carpi radialis tendon sheath and suspensory desmitis.

Treatment consists of box rest and controlled exercise for up to 6 months, combined with intrathecal administration of hyaluronan and corticosteroids. The prognosis for horses with simple injuries is fair. Six of eight horses with

Fig. 75-1 • **A**, Transverse ultrasonographic image of the carpal sheath of a 9-year-old dressage horse with chronic left forelimb lameness of 3 months' duration. Medial is to the left. There is thickening of the sheath wall and enlargement of the superficial digital flexor tendon (SDFT), but no internal structural abnormality could be defined because of the normal heterogeneous echogenicity of the tendon at this level from muscle tissue. The horse failed to respond to intrathecal medication or endoscopic debridement of the proliferative synovial membrane. **B**, Transverse T2* gradient echo magnetic resonance image of the carpus at the level of the musculotendonous junction of the SDFT of the left (shown on the left) and right forelimbs of a horse with chronic left forelimb lameness. There is enlargement of the left fore SDFT. Normal muscle tissue is replaced by an area of low signal intensity consistent with fibrosis (arrow).

uncomplicated desmitis of the ALSDFT returned to the former athletic function.¹⁰ However, horses with concurrent injuries were more likely to suffer recurrent lameness. Debridement of the torn ALSDFT using a tenoscopic approach combined with rest and intrathecal medication was successful in a trotter.⁹

SUPERFICIAL DIGITAL FLEXOR TENDONITIS

Older horses (>15 years of age) and occasionally Standardbred racehorses may show acute SDF tendonitis within the carpal canal (see Chapter 69).² In the acute stage, the carpal sheath is distended, but the horse may show no palpable abnormality of the SDFT in the metacarpal region or only slight peritendinous edema proximally. Diagnosis is based on ultrasonographic identification of lesions of the SDFT. In some horses, lesions may not be detectable acutely but may become apparent over the next several weeks. Some older horses initially show SDF tendonitis, which progresses proximally to involve the SDFT within the carpal sheath. These horses have a poor prognosis regardless of the method of management.

Younger horses may develop SDF tendonitis in the proximal metacarpal region. Such lesions may extend proximally into the carpal region, with only slight distention of the carpal sheath. A high proportion of these lesions result in recurrent lameness if treated conservatively. In horses with chronic tendonitis, surgical treatment by desmotomy of the ALSDFT combined with transection of the carpal retinaculum and proximal metacarpal fasciotomy should be considered (see Chapter 69). Moderate results have been achieved in a small number of racehorses and ponies.⁹

INJURY OF THE SUPERFICIAL DIGITAL FLEXOR TENDON AT THE MUSCULOTENDONOUS JUNCTION

Rupture of the SDFT at the musculotendinous junction is usually the result of a fall and is a catastrophic injury meriting humane destruction of the horse. There is rapid development of soft tissue swelling in the antebrachium. The horse is severely distressed and is unable to fully load the limb, and if it tries to do so there is abnormal sinking of the fetlock. Diagnosis is usually made based on the results of clinical examination.

Focal tears of the SDFT at the musculotendinous junction occur rarely and result in moderate to severe lameness associated with distention of the carpal sheath. Diagnosis is based on ultrasonographic examination,⁵ which may not be straightforward because the normal muscle tissue is anechogenic. Hematoma formation may be seen as a region of increased echogenicity. Careful comparison with the contralateral limb reveals that the tendon is enlarged, and there may be echogenic material extending from the tendon margins, reflecting tearing. Horses with low-grade lesions within the musculotendinous junction may respond favorably to conservative management but those with large tears warrant a more guarded prognosis. Surgical debridement, performed tenoscopically, has yielded disappointing results, with most horses remaining lame despite prolonged rest.

INJURY OF THE FLEXOR RETINACULUM

Primary injury of the flexor retinaculum is rare but does occasionally occur. More commonly, thickening and loss of echogenicity are seen ultrasonographically in association with other injuries, such as desmitis of the ALSDFT, carpal sheath tenosynovitis, or SDF tendonitis.

DEEP DIGITAL FLEXOR TENDONITIS

Primary deep digital flexor (DDF) tendonitis within the carpal sheath is unusual, but marginal tears have been identified endoscopically in a small number of horses with persistent lameness associated with carpal sheath distention. Surgical debridement has resulted in clinical improvement. Secondary tears on the cranial aspect of the DDFT may occur with a solitary osteochondroma or a distal radial physeal exostosis (see the following sections). Carpal sheath distention with incomplete rupture of the cranial head of the DDFT has been reported.¹² Hemorrhagic fluid was aspirated from the sheath, and disruption of the DDF muscle was identified by ultrasonography.

Occasionally DDF muscle injuries occur proximal to the carpal sheath, resulting in localized swelling and lameness. Ultrasonography is required for definitive diagnosis.⁵ Acute injuries result in a region of reduced echogenicity reflecting muscle tearing and hemorrhage, whereas a more chronic injury may be hyperechogenic reflecting hematoma formation or fibrosis. Off-incidence artifact can be used to differentiate between a hematoma and fibrosis.

SOLITARY OSTEOCHONDROMA

An osteochondroma is an exostosis continuous with the cortex of the bone and is covered by cartilage. The distal caudal radius is a common site, immediately proximal to the distal radial physis. An osteochondroma is readily identifiable radiologically and by ultrasonography. Almost invariably an impingement lesion is found on the cranial aspect of the DDFT. Treatment is by surgical removal of the osteochondroma and debridement of any torn fibers of the DDFT. Treatment usually produces an excellent functional and cosmetic result.²

DISTAL RADIAL PHYSEAL EXOSTOSES

Small spikes or exostoses may develop on the distal caudal aspect of the radius at the level of the physis.¹¹ These vary in size and have the potential to create tears in the cranial aspect of the DDFT (Figure 75-2). Importantly, it is the exostoses that occur on midline and not those that can be seen peripherally on oblique radiographic images that irritate and injure the DDFT. Careful examination of a dorsopalmar radiographic image of the carpus is required. Although some can be identified radiologically, others are only identified using ultrasonography. A typical history is of sporadic severe lameness that frequently resolves very rapidly (within hours). The carpal sheath may be mildly to moderately distended at the time of lameness, but in some horses there are no detectable localizing clinical signs, creating a diagnostic challenge. Surgical removal of the spike and debridement of torn tendon fibers usually yield an excellent prognosis.

Fig. 75-2 • A, Lateromedial radiographic image of the distal radius of a 7-year-old Warmblood dressage horse with sporadic severe lameness, associated with distention of the carpal sheath. There is a physeal exostosis (arrow) on the caudodistal aspect of the radius that was impinging on the deep digital flexor tendon (DDFT). **B,** Longitudinal ultrasonographic image of the carpal sheath obtained from the caudomedial aspect. Proximal is to the right. There is an exostosis (arrow) impinging on the DDFT.

FRACTURES OF THE ACCESSORY CARPAL BONE

Fractures of the accessory carpal bone are often the result of a fall and result in acute-onset, moderate to severe lameness (see Chapter 38). The majority have a vertical configuration.^{14,15} Reports are conflicting about the incidence of carpal canal syndrome secondary to a fibrous union or non-union of the accessory carpal bone.¹⁴⁻¹⁶ Seven of 11 horses returned to full athletic function without complications after a vertical (frontal) fracture of the accessory carpal bone, despite healing by fibrous union in the six horses reexamined radiographically.¹⁵ The four remaining horses were

sound; two were retired for breeding, and two were used for pleasure riding. I have had similar experience. However, if lameness associated with thickening of the carpal sheath wall persists, resection of a piece of the carpal retinaculum may be successful.¹⁴ Radiographs should be inspected carefully because occasionally chip fractures of the articular margin of the accessory carpal bone occur alone or concurrently with a more typical vertical fracture. Horses with such fractures warrant a more guarded prognosis. Small chip fractures may be removed surgically, but osteoarthritis of the antebrachiocarpal joint may rapidly ensue. Horses with severely comminuted fractures warrant a guarded prognosis.

Chapter 76

The Tarsal Sheath

Eddy R.J. Cauvin

The tarsal sheath corresponds to the synovial sheath of the lateral digital flexor tendon at the level of the hock. Tenosynovitis of this sheath is a well-recognized condition¹⁻⁶ and can be caused by a wide range of lesions. Nonpainful, chronic distention in the absence of obvious pathological lesions, often called *idiopathic thoroughpin*, is common and should be distinguished from other debilitating causes of tenosynovitis, many of which can cause persistent, severe lameness.^{7,8} Specific lesions within the sheath can be difficult to confirm clinically.^{8,9}

FUNCTIONAL ANATOMY

The deep digital flexor tendon (DDFT) in horses is formed by the fusion in the proximal metatarsal region of the thin medial digital flexor tendon and the larger lateral digital flexor tendon.¹⁰⁻¹³ The two tendons pass within separate sheaths. The lateral digital flexor muscle covers the caudal aspect of the tibia and is joined by the tibialis caudalis muscle in the distal aspect of the crus. The tendon starts 2 to 4 cm proximal to the tarsocrural joint and passes medial to the tuber calcanei over a fibrocartilage-covered groove on the plantar aspect of the sustentaculum tali of the calcaneus. The lateral digital flexor tendon passes over the thick plantar ligament on the distal, medial aspect of the tarsus, medial to the superficial digital flexor tendon (SDFT), before being joined by the medial digital flexor tendon 1 to 3 cm distal to the tarsometatarsal joint.

The tarsal sheath is 16 to 20 cm long and starts near the musculotendonous junction of the lateral digital flexor

Fig. 76-1 • Transverse section of the proximal tarsus, showing the lateral digital flexor tendon (LDFT) in the fibrocartilaginous groove (F) on the plantar aspect of the sustentaculum tali (Sust). Lateral is to the left. Vessels and nerves course within the retinaculum (2), lateral to the attachment of the mesotendon (1). MDFT, Medial digital flexor tendon; SDFT, superficial digital flexor tendon.

tendon in the distal caudal aspect of the crus. At this level the tarsal sheath forms a large pouch between the lateral digital flexor muscle and the common calcanean tendon. The distended pouch is largest over the lateral aspect of the crus. At the level of the tarsocrural joint the sheath extends laterally to surround the lateral digital flexor tendon. Cranially a rigid groove is formed by fibrocartilaginous thickening of the tarsocrural joint capsule. The sheath terminates as a recess dorsomedial to the DDFT in the proximal third of the metatarsal region.

The tarsal sheath is enclosed at the level of the sustentaculum tali by a thick, transversely oriented ligament, the plantar retinaculum (Figure 76-1), and in the distal tarsus by a superficial fascia. The plantar nerves and vessels run within the retinaculum, in the plantar two thirds of its width, that is, plantar and plantaromedial to the lateral digital flexor tendon. The sheath is lined by a parietal synovial membrane with few villi, except distally. This membrane reflects plantarly to wrap around the tendon, leaving a thin but continuous membrane, or mesotendon, along the plantaromedial aspect of the lateral digital flexor tendon. This membrane carries vessels to the tendon and therefore should be preserved during surgery.

CAUSES OF TARSAL TENOSYNOVITIS

Distention of the tarsal sheath (Figure 76-2) is commonly termed *thoroughpin*, or *true thoroughpin*,¹⁴ but the condition may have distinct causes (see Figure 6-30).

Idiopathic Thoroughpin

Slight to moderate distention of the tarsal sheath is often seen in young horses.^{8,9} It also occurs in adults, particularly in Warmbloods and Western performance horses and horses with a straight hock conformation, after extended box rest

Fig. 76-2 • Distention of the tarsal sheath, giving the typical thoroughpin swelling, medially in the distal caudal aspect of the crus and proximal metatarsal region (white arrows) and laterally, caudal to the tibia (black arrow).

or transport. Effusion also may result from acute inflammation in nearby tissues, congestion, and edema in the distal limb (sympathetic effusion). The distention usually is not associated with signs of inflammation or lameness and tends to resolve spontaneously.⁸ However, the distention can become recurrent or persistent in some horses.

Traumatic Thoroughpin

Tenosynovitis may be induced by trauma, leading to acute inflammation and hemorrhage in the sheath. In my experience, direct trauma to the medial plantar aspect of the sheath is common and most often results from a kick by another horse. Tenosynovitis also may result from hitting hard objects during jumping or occasionally from interference from the contralateral hind foot. These traumatic injuries may be associated with a chip fracture or fragmentation of the medial edge of the sustentaculum tali at the insertion of the plantar retinaculum.^{3,13} Transverse fracture of the calcaneus involving the sustentaculum tali also was described.³ In most horses no signs of direct trauma are apparent, and overstretching, or sprain, which may or may not involve the lateral digital flexor tendon, is suspected of causing acute tenosynovitis.^{8,9} Intrathecal hemorrhage always causes substantial inflammation and pain and can induce the formation of fibrinous adhesions. The inflammation often leads to chronic distention, with synovial thickening, fibrosis, and fibrous adhesion formation between the lateral digital flexor tendon and parietal sheath lining, which occasionally can cause persistent pain and mechanical lameness. Acute tenosynovitis without overt lameness also has been described.⁹

Primary Lateral Digital Flexor Tendon Injuries

Sprain injuries to the lateral digital flexor tendon do occur in the tarsal sheath region and are characterized

ultrasonographically by longitudinal fraying and irregular hypoechoic lesions at the level of the sustentaculum tali. These lesions may be caused by overstretching and compression of the tendon over the bone.

Infectious Tenosynovitis

Direct trauma to the medial aspect of the hock can result in breach and contamination of the tarsal sheath.^{3,9,13,15} The medial edge of the sustentaculum tali is the most prominent relief on the medial aspect of the tarsus, and a wound at this level often disrupts the retinaculum, thus opening the sheath.^{6,13} Puncture wounds are rare in my experience, but they may occur, especially in the distal caudal aspect of the crus. Iatrogenic contamination induced by intrathecal injection is also common and should be suspected in horses with worsening of the lameness and signs of inflammation after such injections.⁹ If untreated, suppurative tenosynovitis may lead to infectious tendonitis, destruction of the fibrocartilage, and eventually osteitis or osteomyelitis of the calcaneus.^{3,4,6,13} Infection also may result from extension of abscesses in adjacent tissues.

Other Causes

One horse with hemangiosarcoma involving the tarsal sheath has been described.⁷ Chondrosarcomata, extending from the tarsocrural joint, and systemic lupus-like synovitis have been reported as rare causes of thoroughpin.⁹

DIAGNOSIS OF TARSAL SHEATH INJURIES

Clinical Signs

Distention of the tarsal sheath is visible in the distal aspect of the crus, particularly laterally between the common calcanean tendon and the tibia and, to a lesser extent, on the medial caudal aspect of the crus (see Figures 6-30 and 76-2). Such distention should not be confused with swellings associated with the plantar pouch of the tarsocrural joint (see Chapter 44), situated farther distally between the tuber calcanei and distal aspect of the tibia (bog spavin) or with distention of other bursae, for example, the deep calcanean bursa and calcanean bursa of the SDFT (see Chapter 79).^{8,10} False thoroughpin may result from soft tissue masses such as hematomata, tarsal sheath herniation, granulation tissue,^{8,9} or abscesses (see Chapter 79). Distention of the tarsal sheath also may be detected in the proximal metatarsal region on the medial aspect of the DDFT.

In horses with idiopathic tenosynovitis, the swelling is soft and nonpainful and unassociated with lameness.^{9,16} In inflammatory conditions, swelling is soft, warm, and painful in the acute stage and nearly hard and rarely painful in chronic injuries. The degree of lameness varies.^{3,7} The level of pain is not always correlated with the severity of the condition. Prominent pain usually is induced by hock flexion in acute and chronic injuries, and the degree of hock flexion may be greatly decreased. Confirming that the lameness is associated with the sheath may be necessary by using intrathecal injection of 5 to 10 mL of local anesthetic solution and by elimination of other sources of pain. Synoviocentesis may be difficult in horses with acute injuries because of edematous, hypertrophic, and congested synovial membrane.

Confirming infection is not always easy in all horses in the absence of a wound. Wounds over the sustentaculum tali always should be considered suspicious and warrant a contrast tenovaginogram or tenovaginoscentesis.

Radiography

Radiographic examination is paramount in all horses with severe tarsal tenosynovitis to rule out fractures or osteitis of the sustentaculum tali and tuber calcanei (see Chapter 44).^{2-4,13} Lesions are most visible on dorsoplantar and dorsomedial-plantarolateral oblique images to highlight the medial and plantaromedial aspects of the calcaneus (Figure 76-3). A flexed skyline image of the plantar aspect of the sustentaculum tali (flexed proximocaudal-distoplantar image) is essential to demonstrate some lesions¹⁷ (Figure 76-4). Contrast radiography is also useful to highlight the surface of the fibrocartilage and the outline of the lateral digital flexor tendon¹⁸ but has been replaced largely by ultrasonography.¹² However, contrast radiography remains a useful technique to confirm puncture wounds into the sheath. After collecting synovial fluid, 5 mL of an iodinated contrast medium mixed with 5 mL of Hartman's solution is injected in the proximal pouch of the sheath, and lateromedial, dorsomedial-plantarolateral oblique, and dorsoplantar radiographic images are obtained to highlight a communication with the skin.

Fig. 76-3 • Dorsomedial-plantarolateral oblique radiographic image of the calcaneus, showing erosion (plain arrow) and fragmentation (dotted arrow) of the edge of the sustentaculum tali.

Fig. 76-4 • Skyline radiographic image of the calcaneus, highlighting fragmentation of the edge of the sustentaculum tali (arrow), medial to the groove.

Ultrasonography

Ultrasonographic examination of the tarsal sheath is best performed with a linear 7.5-MHz or higher-frequency transducer. The lateral digital flexor tendon is best imaged from the medial aspect of the limb.^{12,13,19} Accurate imaging requires high-definition equipment and experience. The chestnut can be trimmed and soaked with warm water to improve imaging. In idiopathic distention, the sheath is filled with anechogenic fluid, and no evidence of synovial membrane hyperplasia is apparent. In acute tenosynovitis, the sheath is distended, and substantial thickening of the synovial membrane occurs. Hemorrhage is seen frequently as a hypoechogenic, whorl-like structure in the proximal pouch. Lesions may be seen in the lateral digital flexor tendon, but they are relatively rare. Longitudinal tears and superficial fraying are the most common types of lesions, but they should not be confused with hyperplasia of the visceral synovium covering the tendon. Early fibrinous adhesions may be visible. The integrity of the fibrocartilage groove and retinaculum can be assessed, and fragmentation of the edge of the sustentaculum tali may be detected.^{8,13} In chronic injuries, substantial fibrosis may be seen around the sheath, and often there are large adhesions between the lateral digital flexor tendon and parietal sheath, especially in the proximal pouch (Figure 76-5). The visceral lining is usually thick (several millimeters) and has increased echogenicity. Horses with chronic lameness and those that have received numerous injections of

Fig. 76-5 • Transverse ultrasonographic image of the tarsal sheath at the level of the tarsometatarsal joint obtained from the plantaromedial aspect. Plantar is to the left. There is hyperplasia of the synovial membrane around the lateral digital flexor tendon (LDF) and a well-organized adhesion between the tendon and parietal sheath wall (arrow). The tarsal sheath (TS) is distended. MCL, Medial collateral ligament; MT2, plantar border of the second metatarsal bone; MDF, medial digital flexor tendon.

corticosteroids may have large, nodular fibrocartilaginous or partially mineralized masses, termed *ossicles*.^{2,9} Differentiating these from chip fractures or mineralization of the tendon or sheath lining without the use of tenoscopy may be difficult. Ultrasonography can help to differentiate true from false thoroughpin (see Chapter 79). Infection is characterized by severe inflammation of the synovial lining, and the fluid is often echogenic and heterogeneous because of the fibrin clots and debris.^{6,13} This may not be obvious early in the condition.

Tenovaginoscentesis

Tenovaginoscentesis (collecting fluid from the tendon sheath) is useful to rule out infection and confirm inflammation.^{9,15} The fluid may be normal in appearance, but it is usually contaminated by blood. A moderate increase of cellularity (<8000/mcL) may be evident, except in horses with acute traumatic injuries where the nucleated cell count can exceed 10,000/mcL. Generally infection is associated with a thin, cloudy to purulent fluid and cell counts well in excess of 10,000/mcL. Note that centesis should be carried out after ultrasonography to avoid bleeding and gas artifacts.

Tenoscopy

Tenoscopy (see Chapter 24) is rarely necessary as a purely diagnostic method because the tarsal sheath is evaluated adequately with ultrasonography in most horses. A major exception is in infectious conditions, where it may be useful to assess potential damage to the fibrocartilages, which may not be visible with other diagnostic imaging methods.^{13,20}

MANAGEMENT OF TARSAL TENOSYNOVITIS

Idiopathic and Traumatic Tenosynovitis

Treatment is of little value in horses with idiopathic tenosynovitis, which generally resolves spontaneously.^{8,9,16}

Reduced (but not interrupted) exercise, sweats, and systemic antiinflammatory therapy can be helpful.⁹ It is not advisable to place a needle in the sheath because this may cause bleeding and subsequent inflammation.

Treatment of acute tenosynovitis is controversial. In the absence of tendon or bony lesions, rest, systemic or local nonsteroidal antiinflammatory drugs (NSAIDs), local dimethylsulfoxide creams, and cryotherapy (ice packs or cold hosing) are often effective.⁹ The horse should be rested in a box for 24 to 48 hours and then walked out in hand to reduce sheath fibrosis. Hyaluronan may be useful for horses with more severe tenosynovitis or in horses in which lateral digital flexor tendon lesions are present. Intrathecal corticosteroids may be useful in horses with acute tenosynovitis, but they certainly are contraindicated if tendon lesions exist. The latter carry a poor prognosis, except for superficial fraying.^{8,9} Bone fragments should be removed by tenoscopy because they can cause chronic inflammation and interference with the tendon.

In horses with more chronic tenosynovitis with associated lameness, corticosteroids such as methylprednisolone acetate (40 mg), triamcinolone acetonide (10 mg), or betamethasone have been used with varying success.^{8,9} Fluid retrieval to decrease the volume of the sheath, followed by rest and the application of pressure bandages may produce temporary relief of the distention,⁹ but recurrence is common, probably because of chronic proliferative synovitis. Recurrent swelling is often worse than originally seen. Repeated injections have been associated with mineralization of the tendon and synovial lining, and rupture of the lateral digital flexor tendon was reported⁹; therefore repeated injections are not recommended. If possible, the cause of the chronic inflammation should be ascertained. With bony fragments, ossicles, or adhesions, conservative treatment and medical therapy are often disappointing, and surgical debridement appears to be the most effective treatment.^{9,13} Debridement is best achieved by tenoscopy (see Chapter 24) (Figure 76-6). NSAIDs are administered for 1 to 2 weeks postoperatively, and the horse is restricted

to box rest for 10 days, after which handwalking starts several times daily. The horse may be turned out in a small paddock or ridden gently after 2 to 3 weeks. Hyaluronan may be injected intrathecally at least 10 days after surgery.

Infectious Tenosynovitis

Horses with acute infectious tenosynovitis may be treated by thorough lavage of the tarsal sheath, with 5 L of sterile, polyionic isotonic fluids, through large-bore catheters or needles placed in the proximal pouch and distal recess of the sheath.^{9,15} Lavage may be carried out in the standing horse, but it is best performed with the horse under general anesthesia for accurate needle placement and use of a high-velocity, high-pressure lavage system. This technique is less useful if purulent material, adhesions, or bony lesions are present. These horses are best treated by tenoscopic lavage and debridement.¹³ All debris and hypertrophic synovium, frayed areas on the lateral digital flexor tendon, and lesions on the sustentaculum tali (Figure 76-7) are debrided, preferably using motorized equipment, and bone fragments are removed. Drains are rarely necessary, except with recurrent infectious tenosynovitis, but in horses with chronic lameness, leaving a 2- to 4-cm incision (the endoscopic portal) open for drainage is advisable. If a wound is present at the level of the sustentaculum tali, this may be used as an endoscopic portal and then enlarged and left to heal by second intention. Drainage can be prolonged, and primary closure and use of a closed suction drain may be preferable. Fragmentation and osteitis of the sustentaculum tali outside the sheath are best approached through a separate incision. Curettage to the level of healthy bone is performed. Damage to the long medial collateral ligament of the tarsus should be assessed. Aminoglycoside antimicrobial drugs may be inserted into the tarsal sheath at the end of surgery. The horse is treated with systemic broad-spectrum antibiotics (see Chapter 65) for at least 2 weeks postoperatively. NSAIDs are used for at least 5 days and may be continued as necessary. A pressure bandage is applied from foot to midcrus

Fig. 76-7 • Tenoscopic view of the tarsal sheath at the level of the sustentaculum tali (Sust). A small erosion in the fibrocartilage (plain arrow), surrounded by fibrinous pannus (dotted arrow), is secondary to subacute infectious tenosynovitis. LDFT, Lateral digital flexor tendon.

and changed every 1 to 3 days, depending on the amount of exudate produced. The horse should be rested in a box until the wound has healed and then walked out in hand for 2 to 3 weeks before being turned out in a small paddock.

In horses with chronic infectious tenosynovitis with substantial damage to the fibrocartilaginous groove on the sustentaculum tali or to the lateral digital flexor tendon, open surgery was advocated.^{6,8} The tarsal sheath is approached through a desmotomy (longitudinal transection) of the flexor retinaculum to debride all the lesions, followed by the application of a fenestrated drain and repeated lavages for several days. The retinaculum is left unsutured to relieve pressure, and the skin is closed over it.⁶ A tenectomy of the damaged lateral digital flexor tendon within the sheath was performed in one horse unresponsive to this approach. However, this was associated with clinically significant complications from poor healing of the wound. In another horse, midmetatarsal tenotomy of the DDFT was carried out, with a heel extension shoe applied to prevent digital hyperextension. This decreased the lameness, presumably by decreasing shearing of the lateral digital flexor tendon on the roughened sustentaculum tali. In my opinion, most horses respond to tenoscopic treatment. More

aggressive techniques should be reserved for horses that are unresponsive or those with severe damage to the tendon.

Prognosis

The prognosis is good in horses with idiopathic thoroughpin,^{8,9,16} although some horses may have persistent, non-painful distention of the tarsal sheath. In these horses surgery to imbricate the stretched synovial sheath has been advocated,⁹ but recurrence is common. The prognosis is fair in horses with acute tenosynovitis treated medically^{8,9} and in horses with chip fractures of the sustentaculum tali treated by tenoscopy.¹³ In chronic traumatic tenosynovitis, some horses may respond to a single injection of corticosteroids,³ but most have recurrent distention and lameness caused by adhesion formation and peritenovaginal fibrosis. These may respond well to tenoscopic treatment,¹³ but a guarded prognosis should be given if lameness is a prominent feature. In horses with infection the prognosis is fair with prompt drainage and curettage, but poor in horses with severe tendon lesions or extensive damage to the sustentaculum tali.^{2,4,9} A fair prognosis was reported with aggressive surgical debridement in horses with osteitis/osteomyelitis of the sustentaculum tali, even if chronic.²⁰

Chapter 77

Extensor Tendon Injury

Jane C. Boswell and Michael C. Schramme

The extensor tendons of the carpus and digit and the respective synovial sheaths are vulnerable to injury because they lie relatively unprotected in the subcutaneous fascia on the dorsal surface of the limb. This chapter discusses lameness caused by injuries and disorders of the extensor tendons of the carpus and digit. Injuries of the extensor tendons of the hock (gastrocnemius and calcaneal tendons) are discussed elsewhere (see Chapter 80).
